The molecular basis for the action of uricosuric agents is unknown and indeed can scarcely be known until the processes involved in uric acid absorption or secretion in the renal tubule are understood. Small doses of uricosuric agents cause a reduction of uric acid clearance whereas large doses cause pronounced increases in uric acid clearance. This biphasic effect has been attributed to successive inhibition of secretory and reabsorptive processes respectively [220, 222a]. Striking reductions of the miscible pool of uric acid have been demonstrated after administration of adequate doses of salicylates [190], probenecid [291, 292], phenylbutazone [180, 288] and cortisone [192]. These are probably accounted for entirely by the increment in urate excretion. At least in the case of phenylbutazone an increase in uricoly is or of excretion by nonrenal pathways has been excluded. No significant increase in synthesis of uric acid was demonstrable when phenylbutazone was given for a few days [180] but in the case of one of two normal subjects given this drug for a longer time and in two hyperuricemic patients given probenecid [291] the increment in uric acid excretion exceeded the measured decrement in the miscible pool of uric acid. This suggests either mobilization of uric acid not measured within the pool or a concomitant or subsequent increase in rate of synthesis. In the case of corticotropin there is good evidence for increased uric acid production [192, 280, 287] in addition to the urico-uric effect. The possible direct or indirect effects of urico-uric agents on purine synthesis *de novo* and uric acid production deserve further attention.

The clinical effectiveness of urico-uric agents in preventing progression of tophi and indeed in mobilizing uric acid deposits is now well known. Striking examples of reduction in size of visible tophi and of regeneration and recalcification of bone matrix have been published [251-254]. The shift of uric acid balance in tissue from positive to negative occurs as a consequence of lowering of serum uric acid levels to values sufficiently undersaturated to permit dissolution of tophi. In addition the frequency

This drug does not alter serum concentration or renal excretion of uric acid [39] nor does it have any significant effect upon the mobile pool of uric acid or the rate of its turnover [190-193]. A clue to its possible mode of action is provided by its inhibition of uric acid riboside phosphorylase [153] but since the function of this enzyme and the existence of its substrate uric acid riboside are not established in man the mechanism of action of colchicine in gout remains an enigma. Nevertheless its specificity of action in acute gout provides an important diagnostic test. The disadvantage of colchicine is its propensity to cause violent gastrointestinal upsets when given in doses sufficient to terminate an acute gouty attack. Colchicine itself can be given intravenously with good therapeutic effects and less gastrointestinal toxicity [280] and colchicine by oral or intravenous route is considered the drug of choice for acute gout by many physicians.

#### *Phenylbutazone*

This drug is a potent analgesic agent with remarkable effectiveness in the acute gouty attack [29]. It also has potent actions upon renal transport of uric acid. When given in adequate dosage phenylbutazone appears to be as effective as colchicine in acute gout and when used for only a few days for occasional attacks is quite safe. Its advantage over colchicine is that it causes relief of symptoms without producing violent nausea, vomiting or diarrhea. Phenylbutazone is also an inhibitor of uric acid riboside phosphorylase.

#### *Corticotropin and Cortical Steroids*

ACTH and cortisone or newer derivatives thereof are effective in acute gout although not so dependably as colchicine or phenylbutazone [29]. The mechanism of action is unknown. The tendency for a rebound attack to occur upon cessation of therapy has limited enthusiasm for these agents.

### CHRONIC TOPHACEOUS GOUT

In chronic tophaceous gout one employs measures to prevent further accumulations of uric acid and to mobilize existing deposits as well as measures to prevent further acute gouty attacks. One might add as objectives the prevention or reversal of accelerated atherosclerosis or of parenchymal renal disease but at present the influence of therapy upon these processes has not been adequately assessed. In interval gout the therapeutic goals and measures employed are similar but frequently less extensive. Programs are adequate for satisfactory management.

The treatment of tophaceous gout consists principally of the use of uricosuric drugs, regulation of diet and maintenance colchicine although opinion is divided as to the necessity for and virtues of the last two measures in certain patients.

disease and the patient may experience in their place recurring exacerbations of less acute and less paroxysmal joint pain. These symptoms too may be lessened by the regular use of colchicine.

In a series of 31 gouty patients reported by Gutman and Yu [29] daily ingestion of colchicine for 18 months or more resulted in conspicuous reduction in frequency of attacks in 18 and in 13 instances the response has made the difference between virtual incapacitation because of frequent interruption of activities and restoration of full employment. Talbott's [294] experience confirms that presented above.

#### INTERVAL GOUT

The management of interval gout embodies the principles discussed above except that it is frequently not necessary to institute other than general common sense measures in patients early in the course of the disease. For example, in a gouty patient just recovered from the initial attack with only a moderately elevated serum uric acid level and no evidence of tophaceous involvement one is justified in withholding further colchicine or in omitting uricosuric agents until more specific indications arise since the interval between the initial and the second attack may be years and no drug is completely nontoxic.

#### ASYMPTOMATIC HYPERURICEMIA

The incidence of overt gout in hyperuricemic subjects is not known with certainty but may be of the order of 10 to 20 per cent. In the remaining group an occasional patient may develop parenchymal renal disease and some will develop renal stones. Since the majority of asymptomatic hyperuricemic persons appears to suffer no ill effects from this abnormality no treatment is generally indicated. A high fluid intake, control of weight, and avoidance of high purine foods would seem only sensible. The early recognition of a hyperuricemic male in a family in which severe disabling gout is frequent, especially if the gout occurs at an early age, would constitute an indication for more extensive prophylactic measure.

#### SECONDARY GOUT

The treatment of secondary gout is based upon the same principles applied in the management of primary gout with one important potential exception. These patients frequently have basal uric acid excretions of considerable magnitude and the administration of a uricosuric agent must therefore be undertaken with caution if at all, lest renal stone formation or tubular or ureteral blockade with uric acid occur. This is an ever present hazard and also occurs all too frequently following treatment of the primary disease with cancer chemotherapeutic agents, radiation [16] or steroids [169].

of attacks of acute gout may eventually be considerably reduced in patients receiving uricosuric agents, although shortly after institution of therapy acute attacks may be frequent [283]

Any patient with primary gout who shows clinical or roentgenographic evidence of tophaceous involvement should be treated with an appropriate uricosuric agent. In patients with severe renal disease in whom the filtered load of uric acid presented to the tubules is small, use of a potent agent is necessary in order to secure a useful uricosuric effect.

### *Diet*

Since potent uricosuric agents have become available the necessity for rigid dietary control of purine intake is seldom encountered. The major objectives of dietary regulation have therefore become those of common sense such as weight reduction in the large number of gouty patients who are obese and abstinence from high purine foods so as to avoid unnecessary addition of exogenous purine to the uric acid pool. In addition, a moderate limitation of protein intake may be advisable since synthesis of uric acid *de novo* is augmented in both normal and gouty subjects by protein loading [129]. Patients with moderately restricted consumption of protein and purine show an average decline of serum uric acid level of 1 to 2 mg per 100 ml. High fat feedings may influence adversely renal excretion of uric acid [293] through unknown mechanisms. Methylxanthines such as caffeine and theophylline are converted in the body to methyluric acids which play no role in gout. Therefore coffee, tea and other foods or drugs containing methylxanthines need not be restricted. Many patients tolerate alcoholic beverages well. Others find beer or wine much more likely to lead to gouty attacks than distilled beverages. These are highly individual responses.

If the combined use of the general dietary regulations discussed above and a uricosuric agent maintain the serum uric acid level below 5 mg per 100 ml little will be gained by more spartan dietary prescriptions. In patients in whom even large doses of uricosuric agents are not adequate to achieve this goal or in whom tophaceous involvement is severe or rapidly progressive a rigid low purine diet may be indicated. Diets containing about 30 mg purine  $\backslash$  per day are palatable and well tolerated but diets below this figure require omission of most meat and many vegetable items.

### *Maintenance Colchicine*

The daily administration of small doses of colchicine (0.5 to 2.0 mg) is frequently effective in reducing appreciably the number of acute attacks experienced by the patient with gout. In the stage of advanced tophaceous gout acute attacks may be less common than earlier in the course of the

the publication of the historic experiment of A B Garrod in 1848. The first recorded observation of asymptomatic hyperuricemia in a man in whose family gout occurred was made by Folin and Lyon in 1913 [301]. In 1931 A E Garrod [302] classified gout as an inborn error of purine metabolism and suggested that gout would probably prove to be due to a dominant Mendelian factor which is expressed fairly commonly as hyperuricemia but only infrequently as gouty arthritis.

The occurrence of asymptomatic hyperuricemia among family members of gouty patients was emphasized by Jacobson [11] who examined serums from 1 male relative of each of 3 gouty patients comprising 3 sons and 1

SOURCE: C J Smyth [20].

brother and found hyperuricemia in all 3 persons. The first extensive study was that of Talbott [303] who reported in 1940 that 20 per cent of 136 asymptomatic blood relatives of 27 gouty patients had hyperuricemia. In 10 of 27 families at least 1 person in addition to the index patient had a serum urate value in excess of 6 mg per 100 ml.

A number of more recent studies of similar nature has also appeared. These are summarized in Table 21-6. The conclusion appears well established that hyperuricemia is a frequent finding among relatives of gouty patients.

Smyth, Cotterman, and Freyberg [304] have plotted their data on serum urate levels in gouty patients and relatives in a frequency diagram. All their gouty patients had urate levels of 6 mg per 100 ml or greater. The distribution of values among relatives was bimodal for both males and female, the nadirs in these distributions being 6.0 and 5.0 mg per 100 ml respectively. Using these critical levels they classified 10 of 48 male relatives and 11 of 39 females as hyperuricemic. The distribution of hyperuricemic individuals in 19 pedigrees conformed rather closely with expectations if such kindreds were segregated for a dominant autosomal gene for hyperuricemia. If this is the mode of inheritance, the ratio of hyperuricemic to normal offspring of matings in which only

## RENAL STONES

In patients given urico uric agents alkali and large fluid intake should also be administered. The alkali will increase the solubility of uric acid in urine and may counteract the natural tendency of patients who excrete a highly acid urine [29] to form uric acid stones. The bedtime administration of chlorothiazide or acetazolamide may be a useful adjunct in maintaining an alkaline urine.

## SUPPRESSION OF URIC ACID SYNTHESIS

Recently azaserine [137] and diazo-oxy norleucine [138] have been shown to reduce the incorporation of labeled glycine into urinary uric acid, presumably by inhibition of purine synthesis *de novo*. At present these substances are too toxic and their efforts too difficult to control to provide a useful therapeutic avenue but an attractive goal of the future remains that of pharmacologic regulation of synthesis of uric acid *de novo* in the gouty individual.

## DESTRUCTION OF URIC ACID

Recently the infusion of highly purified uricase has been shown to bring about a transient reduction in serum uric acid level in two gouty subjects [296]. This demonstration is of theoretic interest but does not constitute a practical form of therapy at present.

## GENETIC CONSIDERATIONS

Gout has been recognized as a familial disorder from the dawn of medical history. The first recorded expression of this belief is that of Galen (A.D. 131-201) who ascribed gout to debauchery, intemperance and an hereditary trait. Among ancient and more recent writers Cadogan (1675-1726) stood alone among the many who have written on this topic in believing that gout is not hereditary [9].

Modern studies have recorded a familial incidence of gout ranging from 6 to 81 per cent. English observers [297] have reported the familial incidence of overt gout as 38 to 81 per cent in their cases whereas American observers have generally reported lower figures ranging from 6 to 18 per cent in various series [293-299]. The reasons for these differences are not entirely clear although the heterogeneity of the American population may make it more difficult to obtain accurate familial data here than in England. That these reports need not reflect a true difference in inheritance in the two countries is shown by the data of Talbott of Buffalo who has observed a familial incidence in 75 per cent of his cases [300].

The existence of hyperuricemia in overt gout has been known since

with the enzymatic spectrophotometric method of Kalkar and Praetorius. They examined 261 siblings of 32 patients with gout and discovered 71 hyperuricemic individuals as well as 16 definite and 2 doubtful cases of gout among these relatives. Plots of serum uric acid values in both controls and relatives of gouty patients described normal distribution curves. No clear separation could be made between normal and abnormal uric acid values although the mean values for both male and female relatives of gouty patients were higher than the mean values of their respective control series. An attempt was made to fit data on relatives to the sum of two normal distribution curves, a fit which should exist if inheritance were of an autosomal dominant pattern. The data on male siblings conformed satisfactorily but that on female relatives did not unless it were assumed that the heterozygous state were ten times as common as the homozygous normal state in women, an assumption without warrant. They therefore concluded that dominance with incomplete penetrance and recessive heredity were excluded and suggested that cumulative gene action (polymerism) might be operative. This would mean that the level of uric acid in blood was determined by the cumulative contribution of several perhaps many genes and that hyperuricemic individuals represented the extremes of this trait. In this respect hyperuricemia might be compared with tallness, a trait for which definition is arbitrary but which is found more frequently in males and is more pronounced in degree in those with a close relationship to tall males. The hereditary components in stature are best explained on the basis of an interplay between a large number of genetic factors.

The studies of Smyth and Stecher and associates have dealt with different generations within gouty families whereas those of Hauge and Harvald have dealt with siblings of gouty patients. Whatever the precise genetic mechanism or mechanisms underlying the gouty defect it is clear that the trait for hyperuricemia behaves as a dominant factor in most gouty families. An interesting pedigree of a family probably homozygous for the hyperuricemic trait has been published [13].

It is of interest that the three genetic studies discussed above will permit the interpretation of monomerism and autosomal dominance when the analyses are restricted to male, and that Hauge and Harvald have discarded this theory solely on the basis of poor fit of data obtained on female. If indeed penetrance is low in women and expressivity hindered it may be very difficult to choose between dominance with failing expression and polymerism. Such situations defy precise genetic characterization at present.

An estimate of the relative frequency of hyperuricemia and gout may be made from existing data. In a series reviewed by Smyth [20] there were 33 definite cases of gout among 163 hyperuricemic relatives representing predominantly American and Danish families. One may take

one parent is hyperuricemic should be 1:1. There were no hyperuricemic sons among 14 below the age of 16 years. However, when sons above 16 years of age were considered the ratio was 6 hyperuricemic to 7 normal sons. Thus the data concerning male relatives were in agreement with the hypothesis of dominant autosomal inheritance if one assumed that the metabolic change resulting in hyperuricemia is one which is not manifested in males until about the age of puberty. Among daughters of the same matings 4 were hyperuricemic, 10 normal. Two of 6 below 16 years of age and 3 of 4 above 16 years were abnormal. These data on females cannot be used as evidence for an autosomal dominant pattern of inheritance. However, data in females are less easily interpreted since hyperuricemia frequently does not develop even in genetically endowed individuals until after the menopause.

Stecher, Hersh, and Solomon [12] have published data which permit similar analyses. A frequency distribution plot of uric acid values of 137 relatives of gouty persons (excluding spouses) was shifted toward high values in comparison with a similar plot of 1,024 determinations on individuals from the general hospital population. It was also suggestively bimodal, the nadir being 6.0 to 6.4 mg per 100 ml, and 23 of 147 determinations on 137 relatives fell above this range.

Among relatives they observed hyperuricemia in 15 to 21 per cent of mothers, brothers, sisters, and sons, but in none of 45 daughters of index cases. These workers tentatively concluded that hyperuricemia was an autosomal dominant trait with low penetrance in both sexes, but considerably lower in females than in males. When this conclusion was put to numerical test for male offspring only, a correction being applied for small family size, the expected number of hyperuricemic individuals was 31. Actually 26 were found among 51 men. These figures were regarded as showing satisfactory conformity with the expected 1:1 ratio. The data were then used to estimate penetrance. Since 20 hyperuricemic sons were observed where 31 were expected, the penetrance was estimated at about 84 per cent in heterozygote males. And since there were only 8 hyperuricemic females compared with 54 hyperuricemic males, despite nearly equal sex distribution of the 203 individuals of the study, the penetrance was estimated to be about one seventh as high in women as in men, or about 14 per cent. Since not a single daughter of a gouty patient was found to be hyperuricemic among 45 tested, no critical analysis could be applied in the case of female offspring. Both these groups agreed that hyperuricemia could not be attributed to a sex-linked gene, since male transmission was well documented and frequent. Also a recessive genetic transmission pattern was excluded by Stecher et al. on the basis of a probability analysis.

More recently Hauge and Harvald [15] in Denmark have reexamined the problem of inheritance of hyperuricemia. All analyses were performed

creased the affinity of PP ribose P amidotransferase for PP ribose-P or decreased its affinity for ATP or ADP. Either aberration might permit greater than normal synthesis of phosphoribosylamine despite a normal 1 P ribose-P to (ATP + ADP) ratio.

An increase in the availability of glutamine might push phosphoribosylamine synthesis. The effect of high protein diets in augmenting purine synthesis has already been discussed from this viewpoint. If there is a greater than normal availability of glutamine for purine synthesis in gout, it is not reflected in the plasma levels of glutamine [170].

Overincorporation of glycine 1- $C^{14}$  into urinary uric acid has been demonstrated in a sizable percentage of patients with gout. In addition, gouty patients show excessive utilization of AIC for uric acid synthesis, and administered AIC has less of an inhibitory effect upon glycine incorporation into uric acid in gouty than in normal man.

These results have at least one potential common explanation: that of a relative excess of the active ribose compound 1 P ribose-P in the patient with primary gout. A high steady state concentration of PP ribose P would result in generation of additional phosphoribosylamine provided that saturation of the amidotransferase had not already been reached by the existing level of PP ribose P. This would result in the utilization of a larger than normal quantity of glycine. If the various control mechanisms governing interconversion of purine ribonucleotides and synthesis of nucleic acids are competent, prompt conversion to uric acid of surplus purine nucleotides would be the anticipated result. Under these circumstances the activity of 1 P ribose-P amidotransferase would still be viewed as controlling the overall rate of purine synthesis *de novo*, and the rate would be augmented because of elevation of the 1 P ribose-P to (ATP + ADP) ratio.

A high steady state concentration of 1 P ribose-P would also permit conversion of a larger than normal quantity of administered AIC to its ribonucleotide by direct reaction of AIC with this active ribose compound. Prompt conversion of AIC ribonucleotide to purine ribonucleotides followed by cleavage and oxidation of purine bases to uric acid would result in the appearance of a greater percentage of the test dose of AIC in uric acid in gouty than in normal man. In addition, under these circumstances a given quantity of AIC would deplete the supply of 1 P ribose-P less in a gouty than in a normal subject, potentially also explaining the smaller reduction in synthesis of uric acid *de novo* from glycine in the gouty subject when AIC is administered.

An interesting observation potentially constituting a model for study of mechanisms controlling uric acid synthesis *de novo* is provided by studies of Krakoff and Balis [306] who noted that patients given 2-ethylamino-1,4-thiazole promptly showed a remarkable increase in serum and urinary levels of uric acid (while also developing toxic lesions within

<sup>33</sup>/<sub>163</sub> or one fifth, as an estimate of the proportion of hyperuricemic individuals who at any given time will manifest gout. If the estimate [30] is accepted that about 4 per cent of the 12 000 000 arthritic patients in the United States (population, 175 000 000) have gout the incidence of gout would be 274 per 100 000 or 0.27 per cent. The frequency of all persons carrying the genetic determinants of hereditary hyperuricemia would then be of the order of 1.4 per cent or 1 in 71 individuals. The expected incidence, based upon statistical definition of hyperuricemia, would be 2.8 per cent. Talbott [39] found 68 hyperuricemic persons among over 1,500 males tested at the time of routine college medical examinations an incidence of about 1 in 22 individuals (4.5 per cent). These values may not be appropriate estimates in countries such as England and India [30-297] where gout is said to be much more common than in the United States and Scandinavia.

In the study of Hauge and Harvald [15] no linkage was found between predisposition to hyperuricemia and the genes concerned with blood grouping systems ABO, Rhesus MNS P, Lewis Duffy, and Kell.

### HYPOTHESIS REGARDING THE FUNDAMENTAL GOUTY DEFECT

In primary gout considerable evidence now points toward overproduction of uric acid as at least one underlying mechanism responsible for hyperuricemia. According to present concepts sustained overproduction of uric acid can only occur if there is sustained overproduction of purine nucleotides. The key intermediate in the production of purine nucleotides may be phosphoribosylamine for reasons discussed earlier in this chapter.

If phosphoribosylamine does occupy such a critical role then the rate of its synthesis may be an important factor in regulating uric acid synthesis. As a working hypothesis the author would suggest that there is excessive synthesis of phosphoribosylamine in primary gout. The most immediate factors governing the rate of synthesis of phosphoribosylamine will be (1) the activity of its synthesizing enzyme PP ribose-P amidotransferase as determined by the innate characteristics of the enzyme, the quantity of enzyme, the action of inhibiting nucleotides and perhaps other factors; (2) the concentrations of its substrates, namely glutamine and PP ribose-P.

The synthesis of PP ribose-P amidotransferase is undoubtedly under genetic control. The gouty individual might have a greater than normal quantity of the enzyme, perhaps if the magnitude of urate synthesis is a continuous function having a Gaussian distribution in the general population the gouty subject is one very high on the upper limb of the distribution curve. This notion would accord with the genetic data of Hauge and Harvald [13]. Or an enzymatic aberration might have in

occur solely as a consequence of renal<sup>4</sup> retention of uric acid is difficult to harmonize with existing concepts of the disease

## SUMMARY

1 Primary gout is a genetically determined disorder of purine metabolism in which the cardinal feature is hyperuricemia. It is preeminently a disorder of adult males and is characterized both by recurrent attacks of acute arthritis of unknown cause and by a chronic arthritis associated with deposits of urate in joints and other tissues.

2 Hyperuricemia is defined on the basis of statistical analysis of the distribution of serum uric acid values in the general population. In males hyperuricemia is indicated by values above 6.3 mg per 100 ml by colorimetric methods or above 7.5 mg per 100 ml by enzymatic spectrophotometric methods. In females normal values average about 20 per cent lower than in males.

3 Asymptomatic hyperuricemia is approximately five times as frequent as clinical gout in families of gouty persons. Two types of analysis suggest that the incidence of hyperuricemia is 1 to 2 per cent in the general population. It ranged up to 72 per cent in gouty families.

4 Hyperuricemia cannot be attributed to a defect of uricolysis. Evidence suggests that only 2 to 4 per cent of the turnover of uric acid can be attributed to uricolysis in tissues of man, but that perhaps 25 to 30 per cent can be attributed to bacterial breakdown in the gastrointestinal tract. This fraction is possibly increased in hyperuricemic subjects.

5 The renal mechanism for excretion of uric acid has until recently been viewed as one of glomerular filtration followed by tubular reabsorption of all but 5 to 10 per cent of the filtered urates. Renal tubular secretion has now been demonstrated to occur in man, so that interpretation of clearance data in gouty subjects is uncertain. Values for mean net tubular reabsorption of uric acid in gouty subjects are slightly greater than in nongouty subjects at equivalent filtered urate loads. Statistically significant differences in mean values exist between nongouty subjects and asymptomatic hyperuricemic patients, gouty subjects with normal urinary urate excretion and gouty subjects with habitually excessive urinary urate excretion. In the latter group overproduction of uric acid is virtually certain.

6 Overincorporation of glycine or other precursors into uric acid is demonstrable in many cases of gout. Gouty subjects who excrete abnormally large quantities of uric acid have shown overincorporation of labeled glycine into uric acid whenever studied. These patients are representative of about 8 per cent of the gouty population. Gouty subjects who excrete normal quantities of uric acid have shown overincor-

the mouth) The elevation of uric acid production was due to an enhancement of synthesis *de novo* [306-307] rather than to acceleration of catabolism of nucleoprotein purine moieties The incorporation curves of labeled formate and glycine into uric acid resembled those seen in gouty subjects who overexcrete uric acid The oral lesions and the increased levels of uric acid were promptly corrected by administration of large doses of nicotinic acid [306] or nicotinamide [307] and precursor incorporation curves were then again normal Although the mechanisms of these drug actions have not yet been elucidated it is possible that they involve a common point in the pathways of purine and nicotinic acid metabolism viz., PP-ribose-P If thiadiazole blocks endogenous production of nicotinic acid or binding by its ribonucleotide pyrophosphorylase a sparing effect upon PP-ribose-P would result and might lead to an augmented synthesis of phosphoribosylamine and purines at the expense of DPN (a possible explanation of the pellagra-like mouth lesions) Administration of nicotinic acid might now divert PP-ribose-P from purine synthesis toward its normal product, nicotinic acid ribonucleotide This explanation though speculative is provocative from the standpoint of the metabolic defect of gout

An increase in the steady state concentration of PP-ribose-P at the site of PRA synthesis might derive from one of two major groups of defects (1) those capable of resulting in decreased utilization of a given amount of PP-ribose-P in reactions other than that concerned with purine synthesis *de novo* (i.e., generation of phosphoribosylamine) (2) those capable of resulting in excessive production of PP-ribose-P In the latter case gout might be viewed fundamentally as a disorder of pentose metabolism rather than intrinsically as a disturbance of purine metabolism

PP-ribose-P is generated from ribose 5-phosphate and ATP Ribose 5-phosphate has three primary routes of synthesis overactivity of any of which might result in excessive production of ribose 5-phosphate and of PP-ribose-P A possible explanation of the common association of hypercholesteremia and hyperuricemia [308-309] is that both conditions arise from excessive activity of the phosphogluconic acid oxidation pathway increased generation of reduced TPN leading to enhanced cholesterol synthesis and increased generation of ribose 5-phosphate to enhanced synthesis of PP-ribose-P, phosphoribosylamine and purines

These considerations leave open the possibility that genetic effects at different loci might give rise to a common metabolic disturbance manifested as primary gout caution is urged in adopting too readily a unified genetic concept of the disease In this connection it should be recalled once more that gouty subjects do show a low net renal clearance of uric acid Whether this represents a disturbance related in some way to overproduction of uric acid or whether it is an unrelated derangement cannot now be stated although the concept that primary gout might

poration of glycine  $1\text{ C}^{14}$  in about one half the cases studied. These patients are representative of about 68 per cent of the gouty population. Several factors were cited such as greater dilution within an expanded uric acid pool, or greater gastrointestinal loss in the hyperuricemic subjects which might account for an apparently normal glycine incorporation value despite existing overproduction of uric acid. Certain studies of 4-amino-5-imidazolecarboxamide incorporation into uric acid and of the rate of turnover of the uric acid pool strongly suggest that overproduction of uric acid occurs in gouty subjects more frequently than can be demonstrated at present by glycine incorporation studies.

7 Although studies of renal excretion of uric acid and of glycine incorporation into uric acid in gouty subjects show overlap of results with those of nongouty subjects, the mean values of groups indicate significant abnormalities of both in patients with gout. The question is raised whether the metabolic derangement of gout results in excessive production of uric acid and also of some hypothetical substance which interferes with uric acid excretion by the kidney.

8 Overincorporation of labeled precursors into uric acid in primary gout appears to occur by way of a shunt pathway, or pathways by which a percentage of newly formed purine nucleotides is broken down to purine bases which are then promptly oxidized to uric acid. A hypothesis is presented that overproduction of purine nucleotides occurs because of a defect in regulation of synthesis of phosphoribosylamine, the first specific purine precursor. Mechanisms may exist for regulation of the rates of synthesis of adenylic and guanylic acids so that excessive synthesis of their mutual precursor, inosinic acid results in cleavage of the surplus and direct synthesis of uric acid.

9 The mechanisms underlying the acute gouty attack remain unknown. It is not established that crystallization of urate in the synovium is causally related to the paroxysm. Demonstration of alterations in urinary excretion of certain purine bases during the acute attack, and of inhibition of uric acid riboside phosphorylase by colchicine, have drawn attention to possible metabolic causes of the attacks. Chronic gout is related to accumulations of urate in joints and to associated osteoarthritic changes.

10 The heredity of the hyperuricemia of gout is well established. Whether the hyperuricemia is determined by an autosomal dominant gene with incomplete penetrance (monomerism) or by a cumulative gene action (polymerism) remains unsettled. Indeed if the disorder is heterogeneous, as appears likely, different patterns of inheritance may exist.

## Chapter 22

### Xanthinuria\*

---

James B. Wyngaarden

Xanthinuria is a rare disorder characterized by the excretion of very large amounts of xanthine in urine and a tendency to form xanthine stones. The only well-documented case of xanthinuria is that described in 1954 by Dent and Philpot [1]. Their patient exhibited a striking diminution of uric acid in blood serum and urine. Urinary stones composed of almost pure xanthine were first identified by Marcet in 1817 [2]. Since that time approximately thirty additional cases have been reported [3-13]. Many of these patients had normal blood or serum uric acid levels and therefore were clearly different from the patient of Dent and Philpot.

### CLINICAL FEATURES

#### *Case of Dent and Philpot [1]*

This patient was a 4½-year-old girl with hematuria and urinary frequency. X-ray examination led to a strong suspicion of a nonopaque stone. The urine contained no excess of calcium, cystine, or amino acids. The patient passed a smooth oval stone measuring 1.5 × 1.0 × 0.5 cm and weighing 0.9 gm. It was translucent to x-rays, contained only traces of calcium and magnesium, and was almost ash-free. In the murexide test it gave a reddish-brown color quite unlike that of uric acid and rather unlike that given by pure xanthine. A hydrolyzed sample yielded traces of amino acids, suggesting that protein was present to the extent of about 5 per cent of the weight of the stone. Scrapings of the stone were dissolved and analyzed by paper chromatography in the presence of various purine markers. The material from the stone matched exactly pure xanthine. The urine was then examined by paper chromatography.

This work was supported in part by grant A-1331 from the National Institutes of Health, Public Health Service.

and shown to contain large quantities of xanthine and no detectable uric acid

Xanthine excretion by the colorimetric method of Williams [14] was about 176 mg per day, or 607 mg per gm creatinine. These values suggested that xanthine, not uric acid, was the end product of purine metabolism in this patient (see Figs 21 8 and 22 2). However uric acid may have been present in small amounts for when the urine was analyzed by the method of Folin and Trimble [16] it appeared to contain 30 mg uric acid per day.

The plasma was also examined chromatographically. It showed neither uric acid nor xanthine even when five times the amount required to show uric acid in normal plasma was employed. These results indicated that if either uric acid or xanthine was present the level was less than 1 mg per 100 ml. Since normal plasma may contain less than 0.1 mg xanthine per 100 ml, a considerable elevation of this compound might have escaped detection by this method (see below). Standard chemical analysis by the method of Folin and Trimble showed 0.5 mg per 100 ml apparent uric acid.

This patient was restudied at age 9 by Dickinson and Smellie [15a]. She had had no further calculi in the interim but clubbing of the calices of the left kidney and enlargement of the right kidney had been detected and her blood pressure had varied between 120/65 and 140/80. By specific enzymatic methods plasma oxypurines were 0.74 mg per 100 ml and plasma uric acid was <0.2 mg per 100 ml. The renal clearance of oxypurines was 94 ml per min per 1.73 m<sup>2</sup> body surface area, a value equivalent to 82 per cent of the simultaneous endogenous creatinine clearance. Fresh urine and plasma contained small quantities of hypoxanthine equivalent to 10 to 20 per cent of xanthine. Stored specimens showed larger quantities of hypoxanthine and also showed more uric acid than was found in fresh specimens.

#### *Other Cases of Xanthine Stones*

Xanthine stones have been found in patients ranging from 4 to 72 years of age. Three quarters of the 31 reported subjects have been males. Two thirds of the xanthine stones have been 'pure' and one third 'mixed'. The mixed stones have frequently contained uric acid or calcium oxalate or phosphate in addition to xanthine.

In no case of xanthine stone other than that of Dent and Philpot has the urinary excretion of xanthine been measured or hypouricemia reported. In the few studied cases all adults the level of blood or serum uric acid has been normal [4, 10, 13] or even somewhat high [9]. In one of three Duke Hospital cases hyperuricemia and increased urinary uric acid excretion were found (1958) in a patient who had had a mixed xanthine-uric acid stone 15 years earlier. Excretion of xanthine and of

other urinary purines [16] was normal. The family also proved to be hyperuricemic. A second adult patient who had also passed a mixed xanthine-uric acid stone had a normal uric acid level. A third subject, a woman who had passed stones since early childhood, had pure xanthine stones at age 28 (1917). No uric acid analyses were performed and she has since been lost to follow up. (Stone analyses were performed by Heywood Taylor by the murexide method. The author is indebted to Dr. Taylor for permission to cite these unpublished cases.)

An interesting case has been reported by Ichikawa [12] in a 44 year old male who had a left nephrectomy performed after a lengthy history of hematuria and negative preliminary study for urinary calculi. The kidney was grossly normal but on palpation was found to be studded with numerous small nodules. The cut surface disclosed many small holes with brownish granular concretions which were round or oval, smooth and friable. Chemical tests revealed these to be pure xanthine and some tubules contained xanthine casts. No other instances of parenchymal xanthine deposits have been recorded.

An observation of potential significance is that certain of the adults who formed xanthine stones were observed to excrete highly acid urine. pH values of 4.0 and 4.9 were recorded in two instances [9, 18]. In the three Duke Hospital cases, urine pH values ranged from 6.0 to 6.5. Xanthine is highly insoluble in acid urine. A defect in urinary acidification such as that described by Henneman and coworkers [17] in some uric acid stone formers might have led to xanthine or mixed xanthine-uric acid stone formation in certain of the reported subjects.

It is clear that a considerable number of the adults who formed xanthine stones did not have the metabolic defect present in the young girl described by Dent and Philpot. The observation that several had normal or even elevated serum uric acid levels probably excludes a block in xanthine oxidation in these subjects. Indeed, it is not established that they had any defect of xanthine metabolism. It may be suspected, however, that xanthine excretion was elevated in at least one subject whose blood uric acid was high. Normal for a 60 year old male patient reported by Taylor and Taylor [10] had xanthine stones weighing 12 gm. If xanthine excretion were normal in this subject (6 mg per day), these stones would represent quantitative precipitation and retention of the cumulative urinary xanthine excretion of 6 years.

Of the 31 known cases of xanthine stones, 6 occurred in subjects under the age of 15. In no case was stone formation recorded as a familial tendency, and in this group no measurements of serum or urinary xanthine or uric acid were recorded except by Dent and Philpot. It is not possible therefore to determine whether any other cases of defect in xanthine metabolism have been observed among xanthine stone formers, although the younger patients and those with large pure xanthine stones would

and shown to contain large quantities of xanthine and no detectable uric acid

Xanthine excretion by the colorimetric method of Williams [14] was about 176 mg per day or 607 mg per gm creatinine. These values suggested that xanthine not uric acid was the end product of purine metabolism in this patient (see Figs. 21-8 and 22-2). However, uric acid may have been present in small amounts for when the urine was analyzed by the method of Folin and Trimble [15] it appeared to contain 30 mg uric acid per day.

The plasma was also examined chromatographically. It showed neither uric acid nor xanthine even when five times the amount required to show uric acid in normal plasma was employed. These results indicated that if either uric acid or xanthine was present the level was less than 1 mg per 100 ml. Since normal plasma may contain less than 0.1 mg xanthine per 100 ml, a considerable elevation of this compound might have escaped detection by this method (see below). Standard chemical analysis by the method of Folin and Trimble showed 0.5 mg per 100 ml apparent uric acid.

This patient was restudied at age 9 by Dickinson and Smellie [16a]. She had had no further calculi in the interim, but clubbing of the calices of the left kidney and enlargement of the right kidney had been detected and her blood pressure had varied between 120/60 and 140/80. By specific enzymatic methods plasma oxypurines were 0.74 mg per 100 ml and plasma uric acid was <0.2 mg per 100 ml. The renal clearance of oxypurines was 94 ml per min per 1.73 m<sup>2</sup> body surface area, a value equivalent to 82 per cent of the simultaneous endogenous creatinine clearance. Fresh urine and plasma contained small quantities of hypoxanthine equivalent to 10 to 20 per cent of xanthine. Stored specimens showed larger quantities of hypoxanthine and also showed more uric acid than was found in fresh specimens.

#### *Other Cases of Xanthine Stones*

Xanthine stones have been found in patients ranging from 4 to 72 years of age. Three-quarters of the 31 reported subjects have been male. Two-thirds of the xanthine stones have been pure and one-third mixed. The mixed stones have frequently contained uric acid or calcium oxalate or phosphate in addition to xanthine.

In no case of xanthine stone other than that of Dent and Philpot has the urinary excretion of xanthine been measured or hypouricemia reported. In the few studied cases, all adults, the level of blood or serum uric acid has been normal [4, 10, 13] or even somewhat high [9]. In one of three Duke Hospital cases, hyperuricemia and increased urinary uric acid excretion were found (1958) in a patient who had had a mixed xanthine-uric acid stone 15 years earlier. Excretion of xanthine and of

mixture is carefully evaporated to dryness. To the yellow residue are added a few drops of 4 N potassium hydroxide. Uric acid forms a purplish violet color at this stage; with xanthine the color is a bright red-orange. Upon further heating the uric acid sample turns yellow and yields a red-orange residue upon evaporation.

The differentiation of xanthine from uric acid is difficult if ammonium hydroxide is used in place of potassium hydroxide as in the conventional murexide test.

**Phosphotungstic Acid Test** Xanthine does not give a color test with phosphotungstic acid where uric acid yields a deep blue color. Xanthine can be carefully oxidized to uric acid with hydrogen peroxide or dichromate [7] and will then give a positive test result.

**Folin's Phenol Reagent** Xanthine and guanine react with Folin's phenol reagent to give a blue color, but adenine and hypoxanthine do not [23]. Uric acid will react but can be destroyed by heating with  $\text{H}_2\text{O}_2$  without affecting xanthine.

**Spectrophotometric Methods** A small amount of material is dissolved in 0.01 N HCl or 0.01 N NaOH with gentle heat and the spectrum of the solution is examined against an appropriate blank. Xanthine exhibits characteristic spectrums as shown in Fig. 22-1 [9]. Pure xanthine stones should permit

Fig. 22-1 Absorption spectrums of xanthine (I printed from Beaver et al. [9] with permission of the author and the Clirex Inc.)

provisional identification by spectral examination. Upon addition of xanthine oxidase at pH 8.2 the spectrum should change to that of uric acid and by observation at appropriate wavelengths [25-26] the quantity of xanthine present may be estimated. The presence of xanthine in impure stones, particularly those containing uric acid, may be difficult to detect.

constitute the most interesting group in which to search for such a defect.

An early report [18] that serum oxypurine levels are elevated in gout has not been confirmed [19].

### *Other Cases of Hypouricemia*

Hypouricemia occurs in association with a number of inborn errors of metabolism but except in the patient described by Dent and Philpot it appears always to be attributable to failure of renal tubular reabsorption of uric acid. The classic prototype of such a defect is that of the Dalmatian coach hound in which urate and inulin clearances are identical [20]. In man hypouricemia occurs in the de Toni Fanconi syndrome (Chap. 37) and in Wilson's disease (Chap. 25) as a consequence of the renal lesions of these disorders.

An interesting case of hypouricemia has been described by Praetorius and Kirk [21]. They discovered a healthy young man with a plasma uric acid value ranging from 0.2 to 0.6 mg per 100 ml and a urinary output of uric acid of 690 mg per day. Uric acid clearances ranged from 162 to 284 ml per min (normal = 7 to 10 ml per min) and averaged 46 per cent greater than simultaneous inulin clearances. The defect in this subject appears to be that of an extraordinarily high uric acid clearance, possibly including tubular secretion (Chap. 21). The original report also describes an elevated level of "oxypurine" in the plasma of this patient, and in that of his father and son both of whom had normal uric acid levels. Subsequently the high oxypurine levels in these patients were attributed by other authors [22] to breakdown of red cell nucleotides occurring before plasma was separated from erythrocytes. Thus the significance of these elevations of oxypurine levels in this family is unclear.

### *Characteristics of Xanthine Stones*

The majority of xanthine stones have been described as brownish or brown yellow, smooth, round or oval, friable, easily cut with a razor and white and laminated inside. A few have been irregular in shape. They have ranged in size from a few millimeters in diameter to that of a hen's egg [3] and in weight from a few grams to 3 gm [3] or more [10].

Xanthine stones are radiolucent and are generally discerned on pyelography as filling defects only. Occasionally sufficient calcium is entrained within the stone to permit radiographic recognition.

A variety of methods has been used for identification of xanthine in the stone. Most of these leave much to be desired and it is to be hoped that future identification will be made with the highly sensitive and specific methods now available including differential spectrophotometry and paper chromatography.

**Murexide Test.** A small amount of the material is placed in a porcelain evaporating dish, a few drops of concentrated nitric acid are added and the

tion of uric acid (Fig 22 2) <sup>1</sup> The first oxidation step of hypoxanthine is slower than the second one Nevertheless careful studies in vitro have shown that a small but detectable steady state concentration of xanthine does exist during hypoxanthine oxidation [33] This is greater than can be accounted for by intermediate xanthine bound to the enzyme surface and is sufficiently large to constitute a xanthine pool in solution

### XANTHINE OXIDASE

Fig 22 2 Conversion of hypoxanthine to uric acid by xanthine oxidase

Xanthine is formed from guanine by action of guanase. Xanthine must then be acted upon by xanthine oxidase to yield uric acid. Guanase may be found in tissues which lack xanthine oxidase. These include blood [34] and kidney [35] and it is therefore not surprising that urinary xanthine generally appears to have been derived from guanine in isotope labeling studies.

Plasma normally contains 0.1 to 0.3 mg per 100 ml hypoxanthine + xanthine [19, 22] and investigations by enzymatic differential spectrophotometric methods indicate that hypoxanthine is the major component of this pair [36]. Both hypoxanthine and xanthine accumulate in the plasma of shed blood [37] and may be increased 100 fold during standing at room temperature for 48 hr. From 10 to 30 per cent of the increment may be due to xanthine which is presumably derived from catabolism of erythrocyte purine compounds [34]. Urinary excretion of xanthine normally ranges from 2 to 8 g (average 4.1) mg per day [30] and is frequently slightly lower in patients with primary gout [33] or with myeloproliferative disorders [39]. Xanthine + hypoxanthine excretion is not influenced by probenecid in man [40]. This suggests that oxypurine bases are not reabsorbed in the renal tubules by the mechanism responsible for urate reabsorption. The clearance of hypoxanthine + xanthine ranges from 15 to 40 ml per min in man and is therefore three to five times the urate clearance.

pK<sub>a</sub> for hypoxanthine, xanthine and uric acid is 8.8, 7.7 and 7.5 respectively [3]. Therefore at pH 7.4 hypoxanthine and xanthine would be present predominantly in their lactam form whereas uric acid would be present chiefly as the monoalkali salt of a mixed lactam-lactam form.

by these methods although an appreciable increase in absorbance at 292  $m\mu$  upon addition of xanthine oxidase would constitute strong evidence for the presence of xanthine since hypoxanthine is so soluble as to be a most unlikely contaminant of the stone. One should however ascertain by suitable analyses with uricase [25-27] that the increment in absorbance at 292  $m\mu$  does indeed represent generation of uric acid.

**Chromatographic Methods.** A number of paper [28] and column chromatographic systems [16-29] is available for separation and identification of xanthine. Movement of the unknown material in a manner similar to that of known xanthine in several systems would constitute strong evidence for identity of the two substances.

A paper chromatographic method was employed by Dent and Philpot in identifying xanthine in the stone recovered from their patient. It is hoped that semiquantitative determinations of all the urinary purines by paper [16-30] or column chromatographic methods [16-29] will be performed on subjects who form xanthine stones so that possible lesser alteration of excretions of other purine bases may also be evaluated.

## XANTHINE

The origin of xanthine has been discussed in Chap. 21 and its relationship to the broader aspects of purine metabolism is presented there. In mammalian systems xanthine has three known immediate precursors: hypoxanthine, guanine, and xanthosine (or deoxyxanthosine) and it is the only established precursor of uric acid (Fig. 21-8).

Presumably the major precursors of xanthine are hypoxanthine and guanine. Each of these bases is formed from its respective nucleoside by action of purine nucleoside phosphorylase, an enzyme which readily cleaves inosine and guanosine but has only limited activity toward xanthosine. Isotope studies discussed in Chap. 21 have provided evidence for significant early labeling of urinary hypoxanthine and guanine following administration of labeled precursors such as glycine or 4-amino-5-imidazolecarboxamide. These observations indicate that the purine bases are products of cleavage of newly formed nucleotides as well as of older nucleotides derived from catabolism of nucleic acids. In most studies the specific activity of urinary xanthine paralleled that of guanine but in some it followed more closely that of hypoxanthine [29-31]. Thus the predominant precursor of urinary xanthine may be either guanine or hypoxanthine in different subjects. Normally only a very small fraction of the xanthine turnover appears in the urine; the large portion by far serves as a precursor of uric acid.

As pointed out above, xanthosine and deoxyxanthosine are relatively poor substrates for nucleoside phosphorylase and presumably little xanthine originates from these precursors. Xanthine arises from hypoxanthine by action of xanthine oxidase as an intermediate in the forma-

variable rates [52]. The enzyme is strongly inhibited by 6-pteridyl aldehyde [53]. Xanthopterin is oxidized to its 8-hydroxy derivative by xanthine oxidase [20].

#### STUDIES ON THE ACTIVE SITE OF XANTHINE OXIDASE

Xanthine oxidase activity towards purines and aldehydes is inhibited by sulfhydryl poisons and by cyanide. A metal mercaptide group has therefore been postulated as an essential part of the active site of xanthine oxidase [54]. Cyanide inhibition of xanthine oxidase presumably involves formation of a stable ferric-cyanide or molybdo-cyanide complex, but binding studies have clearly shown that such inhibition does not interfere with the ability of the enzyme to bind purines. There is evidence that the isoalloxazine ring of FAD constitutes the purine binding site [33, 54] and possibly also the aldehyde binding site [54]. The competition by boric acid with both hypoxanthine and cyanide for the active site suggests that the metal mercaptide groups and the isoalloxazine ring must be located in close proximity.

Fridovich and Handler [54] have proposed a structure for the active site of xanthine oxidase (Fig. 22.3). The active site contains both FAD moieties, only one of which is oxidizable by oxygen or dyes. The metals at the active site are involved in several bonds, i.e. to an adjacent sulfhydryl and to each of the flavins. Electrons pass from the purine substrates to the first flavin and thence via the metal (ferric?) [11].

## XANTHINE OXIDASE

Xanthine oxidase is one of the most extensively studied enzymes. Its distribution in mammalian and avian tissues varies from species to species. In man xanthine oxidase is found in abundance in liver and small intestinal mucosa [41-42] and possibly in bone marrow [42]. It has also been found in human milk [41] but all other human tissues studied have failed to show xanthine oxidase activity. The  $\pi$  include blood, kidney, spleen, heart and skeletal muscle, lung and pancreas [41-42].

Human liver xanthine oxidase has a substrate specificity identical with that of the bovine milk enzyme [33]. This observation implies that information derived from studies of the latter enzyme are relevant to man and this is fortunate since the great majority of careful studies have been conducted with bovine milk xanthine oxidase.

Xanthine oxidase is a flavoprotein containing molybdenum and iron [43]. Bovine milk xanthine oxidase contains two molecules of flavin adenine dinucleotide, one atom of molybdenum and eight atoms of iron per molecule of enzyme and has a minimal molecular weight of approximately 320,000 [44]. Different FAD/Mo/Fe ratios have been reported for the enzyme obtained from mammalian intestine and liver and avian liver [45] but no observations are available on the human enzyme. The enzyme has a remarkably large number of substrates including (1) purines, (2) aldehydes and (3) pteridines. There is now some doubt that oxidation of DPNH by xanthine oxidase preparations is attributable to xanthine oxidase itself [46].

Purine compounds are oxidized in the 2, 6, or 8 position in the presence of xanthine oxidase. The order in which the oxidizable positions are attacked by xanthine oxidase varies from substrate to substrate. With purine the initial attack is at carbon 6. With hypoxanthine the next attack is directed towards carbon 2. Positions 2 and 8 form a closely related pair and oxidation at one of the  $\epsilon$  carbons leads always to attack at the other partner in the next step [33].

Table 22.1 gives data on relative rates of oxidation of purine derivatives by bovine milk and human liver xanthine oxidases. In addition to the substrates shown, xanthine oxidase attacks adenine [47], 2-hydroxyadenine, 8-hydroxyadenine [48], 2,6-diaminopurine [49], 2-azaadenine, 2-azahypoxanthine [50] and a variety of other substituted purines. It does not attack methylxanthines other than the 1-methyl compound [33]. A variety of purine compounds is adsorbed by the enzyme without being oxidized [51]. The enzyme is competitively inhibited by a number of purine bases [49].

**Other Substrates.** All 31 different aldehydes which have been tested are oxidized to the corresponding acid by xanthine oxidase although at

of an increment in xanthine output. If it is much less than 10 ml per min the calculated plasma level would soon be so high as to be inconsistent with experimental data already cited. Even a total inability to reabsorb xanthine in the renal tubule will therefore not explain excretion of xanthine at a level of 600 mg per gm creatinine.

### *Metabolic Block Mechanism*

According to this hypothesis the xanthinuric patient lacks almost entirely the enzyme xanthine oxidase. Such a lack would no doubt lead to an accumulation of xanthine derived from guanine by action of guanase and possibly from xanthine nucleosides by action of nucleoside phosphorylase. The small amount of uric acid in urine might be attributed to dietary sources to a remaining trace of activity of xanthine oxidase or possibly to an accessory pathway such as cleavage of uric acid riboside [56]. The increase in hypoxanthine and of uric acid in urine on standing possibly represents a dismutation reaction

If xanthine oxidase were lacking one would anticipate an appreciable accumulation of hypoxanthine as well as of xanthine in plasma and urine for there is good evidence that free hypoxanthine is normally an important intermediate in uric acid formation and the major oxypurine base normally present in plasma. Several possible mechanisms may be considered to explain a lack of hypoxanthine accumulation, all quite theoretical. (1) A hypoxanthine oxidase distinct from xanthine oxidase may exist. Such an enzyme has been postulated [57] but never identified. (2) Reutilization of hypoxanthine for nucleoside and nucleotide formation may be so efficient as to keep levels from rising abnormally. (3) Xanthine oxidase may not actually be missing but may be structurally abnormal; it may be able to bind and oxidize hypoxanthine but not able to oxidize xanthine.

The last possibility is suggested by recent evidence that the two-step oxidation of hypoxanthine to uric acid involves release of the intermediate xanthine from the enzyme surface and rebinding of xanthine possibly to different active centers of the first IAD component. Bergmann and Dikstein [58] have suggested that hypoxanthine is bound at N1, N3, and N7 while xanthine is bound at N3, N7, and N9. An inability of the enzyme to bind the purine ring at N9 might render it incapable of acting upon xanthine without interfering with its action upon hypoxanthine. Or alternatively such an enzyme abnormality might permit only very slow oxidation of xanthine with production of only very small amounts of uric acid. If opportunity ever permit examination of liver or of breast milk of a xanthinuric subject for xanthine oxidase activity upon various substrates this possibility would be of great interest to explore.

mercaptide groups which are each single electron acceptors to the second flavin from which they may pass to oxygen or other acceptors. Mercury and cyanide both inhibit by interfering with the ability of the metal mercaptide group to transfer electrons from the first to the second flavin.

This hypothesis would explain the occurrence of purine binding by the cyanide-inhibited enzyme and inhibition by high substrate concentration of purines which would also combine with the isalloxazine ring of the

Fig. 22-3 Proposed structure for the active site of xanthine oxidase. (Modified from Fridovich and Handler [54] with permission of the authors.)

autooxidizable flavin and thus prevent interaction with oxygen or other electron acceptors.

## METABOLIC DEFECTS IN XANTHINURIA

Dent and Philpot [1] suggested that gross xanthinuria with very low levels of uric acid in both plasma and urine might be a consequence either of a block in oxidation of xanthine to uric acid or of a 'deviation' mechanism by which xanthine is excreted in urine too rapidly to allow much of it to be oxidized to uric acid. Dickinson and Smellie [15a] have suggested that both defects are present and have published studies showing a renal clearance of oxypurines approaching that of the glomerular filtration rate in the original patient of Dent and Philpot.

### Renal Deviation Mechanism

The deviation mechanism is not adequate as a single defect to explain the known findings. In a normal adult with a glomerular filtration rate of 120 ml per min, an excretion of xanthine of 6 mg per day, and a xanthine clearance of 20 ml per min, the plasma xanthine concentration would be of the order of 0.02 mg per 100 ml. A person with a similar filtration rate and a total inability to reabsorb xanthine would then excrete only 36 mg xanthine per day, and less if the plasma level declined as a consequence of renal xanthine loss. If the normal clearance of xanthine is greater than 20 ml per min, loss of ability to reabsorb xanthine would lead to even less

doubt add greatly to the burden of xanthine excretion and should be limited. Methylxanthines such as caffeine and theophylline are very much more soluble than xanthine and are not metabolized by xanthine oxidase. There would seem to be no unique reason to prohibit their use in xanthinuric subjects.

### SUMMARY

1 Xanthinuria is a rare disorder characterized by the excretion of very large amounts of xanthine in urine and a tendency to form xanthine stones. There is also a striking diminution of uric acid in serum and urine.

2 In only one case that of a girl studied at 4½ and again at 9 years of age have adequate studies been performed to document xanthinuria and hypouricaciduria. Several additional patients have formed xanthine stones in childhood and may provisionally be considered to have xanthinuria.

3 Many of the adults who have formed xanthine stones have clearly not had the defect of the xanthinuric child for in several instances normal or elevated serum uric acid levels were found. Circumstantial evidence suggests that xanthine excretion may have been excessive in a few but this is unproved. In one case xanthine deposits were found in the renal parenchyma.

4 The metabolic defect in xanthinuria probably involves both an absence of (or at least a defect in function of) xanthine oxidase coupled with a renal tubular defect in reabsorption of xanthine.

5 The genetic factors in xanthinuria are wholly obscure except that an autosomal dominant inheritance is precluded.

### *A Combined Defect*

The studies of Dickinson and Smellie strongly suggest the presence of two defects, namely absence of xanthine oxidase and absence of the renal tubular absorptive mechanism for xanthine. Since human kidney does not contain xanthine oxidase activity [41-42] these authors postulate that a single genetic defect has led to a defect in the synthesis of a specific protein serving as the apoenzyme of two catalysts having different physiologic roles. Alternatively the results raise a question basic to biochemical genetics: does a gene (or genome) control the synthesis of a polypeptide fragment which can serve as a component of two or more larger polypeptide (protein) molecules?

## GENETICS

Thirteen relatives of the xanthinuric subject examined by Dent and Philpot [1] showed no abnormal excretion of xanthine and had normal outputs of uric acid. These included an only sister, both parents, and three surviving grandparents. None gave a history of renal stone, and the parents were not related. No statement regarding genetic factors other than exclusion of an autosomal dominant inheritance is justified at present.

In no instance has more than one case of xanthine stone formation been recorded in a single family. Both sexes have been affected, the sex distribution being 5 males and 1 female under age 15, and about 3:1 in favor of males in adults. Therefore no statement can be made regarding genetic factors involved in xanthine stone formation in general. Indeed the adult cases described may not be dependent upon inherited metabolic factors, since there is presently no compelling evidence that a metabolic derangement exists in many such patients.

## TREATMENT

Prevention of xanthine stone formation in predisposed individual depends upon recognition of the low solubility of xanthine in acid solutions, and of the possible tendency of certain of the affected individuals to excrete a highly acid urine. Dent and Philpot [1] found that 100 ml normal urine at 26°C dissolved 6.7, 6.5, and 16.5 mg xanthine at a pH of 5.8, 7.0, and 8.1, respectively. The  $pK_a$  of xanthine is 7.7, the  $pK_a$  is 10.6 [32].

A high fluid intake and oral alkali in quantities sufficient to maintain an alkaline urine would appear essential. Dietary regulation of purine intake is not indicated in the patient with a normal xanthine output, for xanthine excretion is independent of diet in such patients [16]. However in a patient with a block in xanthine oxidation, dietary purines would no

literature has not revealed any report of the normal urinary excretion of orotic acid. Examination of the urine of 73 human beings, both normal and with a variety of hematologic diseases, has failed to reveal the presence of the compound, with the single exception of the patient who provides the basis for this chapter [1]. More extensive studies with more sensitive methods may modify the generality of this finding.

### *Biosynthesis of Orotic Acid*

The investigations elucidating the biosynthetic pathways leading to orotic acid and its role in the biosynthesis of pyrimidines have been adequately and recently reviewed [6-8] and all the details need not be repeated here. The salient features of what now appears to be the major pathway of pyrimidine biosynthesis *de novo* are summarized in Fig. 23.1. Several alternative pathways have been shown to exist, but at present these seem to be of relatively minor quantitative importance in mammalian tissues.

The first step shown in Fig. 23.1, the carbamylphosphate synthetase reaction, is not unique to orotic acid biosynthesis; it also participates in the synthesis of citrulline from ornithine. An active intermediate, not yet unequivocally identified, is involved [9]. In bacteria the overall reaction is reversible, but in mammals only the portion after the formation of the active intermediates has been demonstrated to be reversible [10]. The next step, the carbamylphosphate transferase reaction, appears at present to be unique to orotic acid biosynthesis. The equilibrium of this reaction lies so far towards carbamylaspartic acid [11] that it is essentially irreversible. Ring closure in carbamylaspartic acid to yield dihydroorotic acid is effected by the enzyme dihydroorotase, and in this instance the equilibrium lies about 2:1 towards carbamylaspartic acid [12]. The oxidation of dihydroorotic acid is carried out by the DPN-linked dihydroorotic dehydrogenase, with the equilibrium lying far towards the left [13]. It is to be noted, despite these equilibrium points to the left, that the probable presence of systems for the removal of DPNH would favor the accumulation of orotic acid if its further transformations were blocked. This is precisely what happens in some bacteria [14], in *Neurospora* [15], and presumably in the patient who is the subject of this chapter [1].

### *Biosynthesis of Pyrimidine Nucleotides*

Normally, orotic acid is converted to the ribonucleotide, orotidylic acid, by reacting with 5-phosphoribosylpyrophosphate under the influence of the specific orotidylic pyrophosphorylase [16]. This reaction is reversible, with the equilibrium being about 9:1 in the direction of orotic acid. Orotidylic acid is then decarboxylated to uridylic acid, a reaction for which reversibility could not be demonstrated [16]. Uridylic acid may then be converted to other pyrimidine nucleotides, as indicated in the

## Chapter 23

### Oroticaciduria\*

---

*Charles M. Huguley, Jr. and James I. Bain*

This chapter describes an abnormality thus far noted only once [1]. It occurred in the child of a consanguineous marriage. It is included in this book because it probably represents a genetically determined disorder of pyrimidine metabolism.

This child developed a severe anemia at age 5 months, characterized by hypochromic erythrocytes and megaloblastic marrow. The disease did not respond to treatment with iron, pyridoxine, vitamin B<sub>12</sub>, folic acid, or ascorbic acid. The most intriguing feature was the passage in the urine of large amounts of crystals which proved to be orotic acid. There was some improvement in all features of the disease after the administration of adrenocorticoids, and almost complete clearing of the evidence of illness after administration of a mixture of uridylic and cytidylic acid.

#### OROTIC ACID

Orotic acid (4-carboxyuracil) was first discovered in cow's milk [2] and has since been isolated from the milk of several species, including man [3]. Even though it is an important intermediate in pyrimidine biosynthesis, orotic acid apparently does not accumulate in any appreciable concentration in animal tissues, since injected C<sup>14</sup>-labeled orotate does not encounter any perceptible metabolic pools in rat liver or blood, and the radioactive orotate disappears as such from the liver within 30 min [4]. The injected radioactive orotate is excreted with unchanged specific activity, and excretion is complete within 2 hr. Using isotope dilution techniques, Smith and Baker [5] were unable to find evidence of orotic acid in plasma, erythrocytes, or leukocytes in normal man. A search of the

This work was supported by grants from the American Cancer Society (E-1R-13J) and from the John A. Hartford Foundation.

understood as a result of studies such as those from the laboratories of Kornberg [17] Ochoa [18] Kennedy [19] Leloir [20] and many others

The figure shows the central position of orotic acid an obligatory intermediate in pyrimidine synthesis *de novo*. Pyrimidine bases derived from other endogenous sources or from exogenous sources may however be utilized for the formation of more complex molecules such as nucleic acid. For example Cannellakis [21] has shown that uracil may be incorporated into ribonucleic acid at rates comparable to those of orotic acid incorporation when the conditions are such that a favorable competition exists between degradative and anabolic pathways. Uracil and thymine have also been shown to react in liver preparations with deoxyribose 1 phosphate to yield the corresponding nucleosides [22].

Two pathways for the formation of thymidine and its phosphorylated derivatives are known. (1) the better established one proceeds from uracil deoxyribonucleotide (or deoxyribonucleoside) by direct methylation to thymidylic acid (or thymidine). (2) the other proceeds from cytosine deoxyribonucleoside (or deoxyribonucleotide) either by methylation and subsequent deamination to the thymine derivatives or by deamination back through the uracil deoxyribonucleoside pathway. The relative importance of these alternative pathways is yet to be completely evaluated for any mammalian tissue but the second is rendered doubtful by the work of Kit and associates [23].

## MEGALOBLASTOSIS

### *The Roles of Vitamin B<sub>12</sub> and Folic Acid*

The established hematopoietic efficacy of vitamin B<sub>12</sub> and folic acid in various types of megaloblastic anemia makes it appropriate here to consider briefly what is known of their biochemical roles.

Evidence has been advanced indicating that vitamin B<sub>12</sub> may play a role in protein synthesis, deoxyribose synthesis, reduction of sulfhydryl groups, methyl group synthesis, and conversion of folic acid to an active form [24-31]. Nevertheless, despite the obvious importance of this vitamin, its exact roles are not clearly delineated.

The biochemical actions of folic acid while still not completely clear are much better known than are those of vitamin B<sub>12</sub>. Folic acid is primarily involved in the transformation or transfer of one-carbon units in a variety of metabolic processes concerned with purines, pyrimidines, amino acids, and probably other metabolites as well [24-26]. It seems appropriate to consider here only its direct connection with pyrimidine biosynthesis which occurs at the conversion of deoxyuridylic acid to thymidylic acid. The mechanism of this reaction has been postulated as a hydroxymethylation or formylation of deoxyuridylic acid through the intervention of the appropriate form of tetrahydrofolic acid (either

Fig. 23.1 Biosynthesis of orotic acid and pyrimidine nucleotides

figure Much remains to be learned regarding these pathways implicit reliance cannot be placed in the generalizations of the figure

Figure 23.1 carries the pyrimidine transformations only as far as the nucleotide level. The ultimate incorporation of the pyrimidine nucleotides into deoxyribonucleic acid, ribonucleic acid, the corresponding nucleoproteins, and various coenzymes occurs by processes just beginning to be

cytoplasm and nucleus of the cell. The resulting cell is gigantic and the distribution of DNA in the nucleus is sparse and delicate. The cell matures with infrequent mitoses and the basophilic RNA remains in high concentration in the cytoplasm.

Other information of particular relevance is the effect of administration of various pyrimidines and purines to patients with megaloblastic anemia. The purines have been ineffective [39]. Orotic acid [42], uracil [43], thymine [44], thymidine [45-49] and a mixture of uridylic and cytidylic acids [42] have all been effective in some cases though not in all. The effects may be incomplete and are usually short lived. In patients who have responded the dose of orotic acid has been 3 to 6 gm per day, that of uracil 15 to 30 gm daily and that of thymine 10 to 15 gm daily. These ratios are in keeping with what might be inferred from the previous discussion of pyrimidine biosynthesis. Of particular interest are two patients [48, 50, 51] with megaloblastic anemia requiring folic acid who responded to 15 gm daily of thymine after failing to respond to 30 gm daily of uracil. This seems to fit with the demonstrated need for folic acid in the methylation of uridylic acid to thymidylic acid.

The previous discussion presents a basis for understanding the effects of these metabolites in folic acid deficiency but because the exact site or sites of vitamin B<sub>12</sub> activity is unknown there is no explanation for the effectiveness of these metabolites in vitamin B<sub>12</sub> deficiency. One would hardly expect that any of these materials given singly would afford a universal or complete relief of the metabolic defects resulting from deficiency of either vitamin B<sub>12</sub> or folic acid. Indeed it is remarkable how much some patients have improved and how long they have been maintained in remission while receiving only one of these metabolites.

It is not to be assumed that the derangement in nucleic acid metabolism leading to formation of a megaloblastic marrow results only from absolute or relative deficiency of folic acid or vitamin B<sub>12</sub>. It must be remembered that at each step in the metabolic chain an enzyme is necessary as well as the coenzyme (the vitamin). A genetic lack of an enzyme at any point in this metabolic chain (Fig. 23.1) would be expected to produce a megaloblastic anemia. It is only recently that the relative amount of such enzymes present in normal human cells has been investigated [5]. Enzyme deficiency could explain several apparently inexplicable cases of megaloblastic anemia which have been reported including the one detailed below.

## CLINICAL FEATURES OF OROTICACIDURIA

Full details of the clinical course of the only case of this abnormality so far reported have been given elsewhere [1]. This child had a normal delivery at full term and no abnormalities were discovered at birth. His health and development seemed normal until the age of 3 months. From

hydroxymethyl or formyl) accompanied or followed by reduction to a methyl group with perhaps either DPNH or tetrahydrofolic acid acting as the reducing agent [32-34]. In considering the over all etiology of megaloblastic anemia it must be realized that folic acid like vitamin B<sub>12</sub> has manifold points of action in the metabolic sequences of the cell. It is not yet possible to say whether or not there is one point which is more critical than others for the normal development of the erythrocyte and other rapidly proliferating cells.

### *Significance of Megaloblastosis*

The outstanding hematologic abnormality in the condition under discussion is the presence of megaloblasts in the marrow. This morphologic abnormality was originally described by Ehrlich [35] in the erythrocyte precursors. Strictly speaking the term *megaloblast* refers to an abnormal nucleated red blood cell. Similar changes however are observed in the granulocytes and megakaryocytes of the marrow in pernicious anemia [36] and in the epithelial cells of the gastrointestinal tract in the same disease [37].

The abnormality is a gigantism of the cell. The nucleus is large and frequently irregular and has a delicate chromatin pattern and large nucleoli. Basophilia of the cytoplasm persists very late as the cell matures. Reisner [38] has written a critical review of the nature and significance of megaloblastic blood formation.

The occurrence of a megaloblastic marrow is usually due to a deficiency of vitamin B<sub>12</sub> or folic acid and in nearly all instances will respond to the administration of one or both of the vitamins. Deficiency may result from dietary lack or from one of several conditions interfering with absorption. Megaloblastosis may also be seen occasionally in circumstances in which the mechanism is not fully understood but is believed to be due in part at least to increased requirements of one or the other of these vitamins [38]. It can also be produced in man by the administration of anti-folic acid or antipurine drugs and in susceptible individuals by the administration of diphenylhydantoin or primidone.

A few cases of megaloblastic anemia have responded to neither vitamin [39-40]. Crystalluria was not described in these cases.

A second approach to the interpretation of megaloblastic changes is that of Thorell [41] who studied the DNA and RNA content of individual megaloblasts at different stages of development. Reisner [38] has reviewed more recent developments. The quantity of DNA in the nucleus is normal but large amounts of RNA persist in the cytoplasm to a very late stage in the development of the cell. It is theorized that the inability of the cell to synthesize DNA rapidly interferes with mitosis. The cell continues to grow and although the rate of production of RNA may also be subnormal large amounts of RNA are gradually deposited in the

At that time or subsequently a variety of diagnostic studies was made. These studies as well as the patient's failure to respond to specific therapy, eliminated a deficiency of vitamin B<sub>12</sub>, folic acid, pyridoxine or iron as the cause of his anemia. Hemoglobinopathy Mediterranean syndrome and De Guglielmo's syndrome (erythremic myelosis) were also excluded.

Fig. 23-3 The lack of effect of parenteral folic acid, vitamin B<sub>12</sub>, and pyridoxine and the partial beneficial effect of corticoids on hemoglobin and reticulocytes in a patient with orotic aciduria.

The course of the disease is detailed in Figs. 23-3 and 23-4. Figure 23-3 shows the failure of response to parenteral folic acid, vitamin B<sub>12</sub>, and pyridoxine. Cortisone induced a partial hematologic remission which was later maintained by prednisone or prednisolone. The marrow abnormalities were affected little if at all.

Throughout the course orotic acid was present in the urine whenever it was examined. If a good fluid intake and urine output were maintained, the freely voided urine would contain no crystals, but large amounts would precipitate on standing. When the intake of fluids was reduced, as always happened when the patient felt ill, voiding would be infrequent and crystals would precipitate in the bladder. On several occasions urethral obstruction developed and on one occasion right ureteral obstruction. Fortunately, the obstructions always cleared when fluid

then until the time of his death at 2 years and 9 months of age he was chronically ill with anemia repeated respiratory infections recurrent diarrhea and crystalluria. Prior to hematologic study he had been placed on a low fat diet which controlled the diarrhea and was given medications which he continued to receive for the rest of his life. These assured a satisfactory intake of iron ascorbic acid folic acid vitamin B<sub>12</sub> liver concentrate and other vitamins.

All ancestors were English or Scottish as far as is known except for one (Fig. 232), a founding, believed to be French in origin who was a

Fig. 232. Pedigree of patient with orotic aciduria.

common ancestor of both parents the great grandfather of the father and the great great-grandfather of the mother. Neither parent nor any of three siblings had anemia abnormality of erythrocytes or orotic aciduria.

When first studied at age 9 months the patient was pale and weak but well developed and apparently well nourished. The clerae were definitely blue. There was torsion of the left tibia outward but no other skeletal abnormality. The tongue had a normal coat. The edge of the liver and the tip of the spleen were just palpable.

A severe anemia was found. The erythrocytes were hypochromic with a striking anisocytosis and poikilocytosis. There were a few nucleated erythrocytes. The reticulocyte percentage was slightly elevated. There was a leukopenia with a monocytosis. The platelet count was normal. The marrow was hypercellular and had striking abnormalities of the megaloblastic type in cells of both the granulocytic and rubricytic series. The urine was negative except for a moderate number of crystals which were later proved to be orotic acid.

Prednisone was discontinued and the patient was permitted to relapse. Figure 23-4 indicates the subsequent response to prednisolone: a moderate reticulocyte rise and improvement in the hemoglobin level, a rise in the white blood cell count and in the percentage of neutrophils. There was a fall in the orotic acid excretion, but the level remained high.

Fig. 23-5. Column chromatogram of patient's urine. Chromatograms of this type were obtained by applying a suitably diluted sample of urine adjusted to pH 8.0 containing approximately 150 to 200 optical density units measured at  $260\text{ m}\mu$  to a  $1 \times 10\text{ cm}$  Dowex 1-chloride column. The column was washed with twice the sample volume of water and eluted with HCl using a continuous gradient elution system [5\*]. The 760-ml mixing flask contained water at the beginning, 435 ml 0.015 N HCl, 200 ml 0.1 N HCl and 100 ml 5% HCl were run successively through the mixing flask from a reservoir under enough air pressure to give a rate of 0.5 to 0.7 ml per min. Then 100 ml 5% HCl was run directly onto the column to remove any uneluted material. Optical density of each fraction was read on a Beckman DU spectrophotometer at 260 and  $285\text{ m}\mu$  but only the  $260\text{ m}\mu$  values are plotted in this figure. The ratio  $285/260$  was used for rapid identification of the peaks. Only two of the peaks gave ratios greater than 1: (1) that centered at tube No. 6 is uric acid with a ratio of 2.6; (2) that centered at tube No. 109 is orotic acid with a ratio of 1.8.

The addition of a mixture of nucleotides<sup>1</sup> effected an excellent reticulocyte rise in the hemoglobin level to normal and a striking reduction in the excretion of orotic acid. The appearance of the erythrocytes became normal and megaloblasts disappeared from the marrow. The child gained weight for the first time in 18 months and lost his apparent retardation in walking, talking, and general activity.

<sup>1</sup> Concentrated from yeast extract by Schwartz Laboratories, Inc., Mt. Vernon, N.Y., containing 110 mg cytosylic acid and 1760 mg uridylic acid per milliliter.

intake was increased. Proof of the identification of these crystals as orotic acid is given elsewhere [7]. Briefly the excreted material corresponded to authentic orotic acid samples with respect to elution characteristics from ion-exchange columns.  $R_F$  values on paper chromatograms

Fig 23-4. Changes in hemoglobin, reticulocytes and urinary orotic acid in a patient with orotic aciduria as influenced by administration of prednisolone and a mixture of nucleotides. Medication is diagrammed in the lowest two segments of the figure. The nucleotide mixture contained uridylic acid 115 mg per ml and cytidylic acid 269 mg per ml.

in several solvent systems, ultraviolet absorption spectrums, melting points of the original material and derivative, and elemental analysis. Determinations were made by fractionation on a Dowex column and ultraviolet spectrophotometric determination of the concentration in the appropriate fractions of eluate (Fig 23-5).

Figure 23-3 also shows the hematologic ineffectiveness of uracil. An attempt was made to observe the effect of uracil on orotic acid excretion, but the technique for collecting 24 hr urine specimens was inadequate at that time. Orotic acid excretion was reduced little, if at all.

separate administration of uridylic and orotidylic acid which might have provided a more definitive localization of the defect

This case also provides an instructive illustration of the negative feed back mechanisms which control the production of intermediates in biosynthetic pathways by regulating either the formation of enzymes or their activity [53]. Such feed back mechanisms have been shown in various microorganisms to control the formation of purine precursors [34] arginine [35] isoleucine [56] and orotic acid [14, 37-39] among

Fig. 23-6. Probable point of metabolic defect and possible sites of feed back control mechanism.

others. Similar mechanisms have been inferred from experiments with avian [60] and mammalian systems [61-62]. The case under discussion seems to be most closely analogous to that described in *Escherichia coli* mutants by Yates and Lardee [63] in which it was found that accumulation of carbamylaspartate, dihydroorotate, and orotate was inhibited by the presence of uracil or cytosine. This inhibition was shown to be the result of the fact that cytidine and especially cytidylic acid are competitive inhibitors of aspartate-carbamyl transferase. The mechanism of inhibition by the cytidylic-uridylic acid mixture of orotic acid accumulation in the patient can only be inferred by analogy, but it seems probable that a control mechanism existed in this patient similar to that described by Yates and Lardee in bacteria. The situation may be summarized as in Fig. 23-6.

Aspartate-carbamyl transferase appears to be the most probable point at which control is exerted. This reaction is favored because it is the first one which is specific for pyrimidine biosynthesis and because it is irreversible. Cytidylic acid is shown in the figure as the most likely controlling material because of its relative specificity as an inhibitor of the transferase, as shown by the work of Yates and Lardee [63]. It should be noted however that Smith and Baker [63] have reported that, in contrast

When prednisolone was then stopped the remission continued but when nucleotides were stopped the patient rapidly relapsed and while in relapse contracted a severe case of varicella which involved the lungs and led to his death. At autopsy no abnormalities were found which might have explained the megaloblastic anemia and oroticaciduria.

As far as has been determined from a search of the literature this case is unique. As indicated above it does not fall into any of the well-defined categories of megaloblastic anemia nor does the megaloblastosis seem to be a secondary phenomenon. While cases of idiopathic vitamin B<sub>12</sub>- and folic acid-refractory anemia have been described [39, 40] the authors have been unable to find a case on record of oroticaciduria or even a note of crystalluria as a feature of megaloblastic anemia.

The recognition of crystalluria in this case was due to the combination of a rather massive excretion of orotic acid and a disinclination of the patient to take much liquid when ill. In other circumstances it might easily have been missed. Nevertheless the urines of 73 other persons have been negative for orotic acid. These included specimens from normal children and adults, both parents and all three siblings of the patient, 19 persons (some in relapse some after therapy) with various types of megaloblastic anemia including intestinal malabsorption syndrome, nutritional megaloblastic anemia and the megaloblastic anemia due to primidone and diphenylhydantoin, as well as Addisonian pernicious anemia, three patients with erythremic myelosis, and patients with a variety of nonmegaloblastic anemias.

## BIOCHEMICAL CONSIDERATIONS

The findings clearly imply a defect in the pyrimidine synthetic pathway *de novo* between orotic acid and uridylic acid (or perhaps cytidylic acid). The region of the block may be further delimited if it is assumed that in man the orotidylic decarboxylase reaction is irreversible, as it is in yeast [16]. Since the equilibrium between orotic acid and orotidylic acid lies far towards the former, a defect in either orotidylic pyrophosphorylase or orotidylic decarboxylase would account for the observed accumulation of orotic acid (Fig. 23.6). There was at least a tenfold preponderance of the orotic acid peak in the urinary chromatogram over the adjacent peaks (Fig. 23.5) and the absorption spectrums of the adjacent peaks showed little resemblance to those of suspected intermediates. Unfortunately an exhaustive characterization of the minor components of the urinary chromatogram was not performed, so that the excretion of small amounts of orotidylic acid or orotidine (which might arise from dephosphorylation of the former) cannot be ruled out with certainty. In any case the excreted materials are probably not strictly relatable in quantity to those occurring at the tissue of origin. The early death of the patient prevented the

to the bacterial enzyme the aspartate carbamyl transferase from human blood cells is not inhibited by cytidylic acid. Obviously either dihydro-orotase or the dehydrogenase might be the point of control, and uridylic acid UDP, UTP, CTP or other compounds derived from them are candidates for the controlling material. Uridine diphosphate has been shown to control the activity of orotidylic decarboxylase [62] in a mammalian system. Extension of such studies as these will probably allow an eventual evaluation of the relative effectiveness of the members of the pyrimidine biosynthetic system as inhibitors of the various enzymes involved.

## GENETIC CONSIDERATIONS

The evidence that this disease is due to the deficiency of an enzyme has been given above. Since symptoms appeared early in life there is strong presumption that the enzyme deficiency was genetic in origin but since no other members of the family are known to have been affected there is no proof that it is genetic. Nevertheless because of the consanguinity of the parents the opportunity was present for the apparent transmission of a recessive trait in the homozygous state in the propositus (Fig. 23.2). If this is what occurred the heterozygous state is not associated with oroticaciduria nor with anemia or morphologic abnormalities of the mature erythrocyte.

## SUMMARY

1 Oroticaciduria has been described once. It was associated with a severe anemia developing in infancy and was characterized by hypochromic erythrocytes and a megaloblastic marrow. There was some improvement in all features of the disease after the administration of adrenocorticoids and almost complete clearing of the evidence of illness after the administration of a mixture of uridylic and cytidylic acids.

2 Megaloblastosis would be expected as a result of failure in pyrimidine synthesis. Relief by administration of uridylic and cytidylic acid is as might be predicted. The subsequent fall in orotic acid excretion is probably attributable to a negative feed back control mechanism as has been demonstrated in bacterial systems.

3 Orotic acid is an obligatory intermediate in *de novo* pyrimidine synthesis. The excretion of large amounts would indicate a block in metabolic progression to orotidylic acid or to uridylic acid. A lack of either orotidylic pyrophosphorylase or orotidylic decarboxylase would account for the observed accumulation of orotic acid.

4 Recently reduced levels of both enzymes were found in the erythrocytes of both parents and two of the surviving siblings of the deceased propositus [64].

## Chapter 24

### Beta aminoisobutyricaciduria\*

---

*H Eldon Sutton*

The development of paper chromatography provided a powerful tool for the recognition of hitherto undetected substances in biologic fluids. Among the first to exploit the potentials of this technique was Dent, who examined urine samples from many normal and diseased persons and recorded the presence of several previously unrecognized substances which form colored products with ninhydrin [1]. Of the substances that he encountered in a number of samples was one which he first designated as T spot and which was later identified independently by Crumpler et al [2] and by Fink, Henderson, and Fink [3] as  $\beta$  aminoisobutyric acid ( $\alpha$  methyl  $\beta$  alanine). Crumpler et al [2] found that readily detectable amounts of  $\beta$  aminoisobutyric acid (BAIB) occurred persistently in the urine of approximately 48 per cent of normal British subjects. They suggested that the rate of excretion is controlled by genetic factors. On the other hand, Fink et al [3] in addition to finding a small number of normal individuals who were high excretors, found that a large percentage of cancer patients also were high excretors. Figure 24-1 shows photographs of two-dimensional amino acid chromatograms, one from a high BAIB excretor and the other from a low excretor.

Since these early papers, both the genetic basis for BAIB excretion and the association of BAIB excretion with certain types of disease have been amply confirmed. Harris [4] studied a series of families in London and reported that some individuals consistently excrete large amounts of BAIB (70 to 300 mg per day) and that these persons tend to occur in the same families. Other studies have confirmed this. On the other hand, BAIB excretion has also been reported in association with certain neoplastic diseases, particularly leukemia [5-10] and with tuberculosis [11], march hemoglobinuria [12], liver disease [13], lead poisoning [14].

Research in the author's laboratory is supported in part by Research Grant A 830 from the National Institutes of Health, Public Health Service.

mongolian idiocy and other types of mental defect [15-17] epilepsy [18] and following heavy irradiation with neutrons and  $\gamma$  rays [19] Several other diseases have been reported with high BAIB excretion but in most cases these have involved too few patients to exclude a chance association with an inherited high excretion of BAIB or else the procedures for identifying BAIB were inadequate Berry [19a] has recently summarized studies of BAIB excretion in a large number of healthy and diseased

Fig 24.1 Two-dimensional amino acid chromatograms of urine from a low BAIB excretor (left) and from a high BAIB excretor (right). An aliquot of urine containing 50  $\mu$ g creatinine was applied in the lower left corner. Color development was with ninhydrin. Abbreviations: alanine (Ala), glutamine (Glu), glycine (Gly), lysine (Lys) and taurine (Tau).

infants. She found that the high excretion associated with diseases is variable and that in some cases it could be influenced by diet. No evidence has been obtained that inherited BAIB excretion is deleterious.

Although BAIB frequently occurs in high levels in urine, it does not occur in sufficient quantities for detection in other body fluids which have been tested (blood, spinal fluid, saliva). It was not found at appreciable levels in urine samples from 55 primates [10]. On the other hand, Tallan, Moore, and Stein [20] reported barely detectable quantities in the liver, brain, and kidneys of a cat. Its occurrence in appreciable concentrations, however, seems limited to the urine of some human beings.

## METABOLIC REACTIONS INVOLVING BAIB

### Relation to Thymine

In their paper on the identity of BAIB, Fink, Henderson, and Fink [3] recognized that the carbon skeleton of BAIB is present in thymine and

## Chapter 24

### Beta aminoisobutyricaciduria\*

---

*H Eldon Sutton*

The development of paper chromatography provided a powerful tool for the recognition of hitherto undetected substances in biologic fluids. Among the first to exploit the potentials of this technique was Dent who examined urine samples from many normal and diseased persons and recorded the presence of several previously unrecognized substances which form colored products with ninhydrin [1]. Of the substances that he encountered in a number of samples was one which he first designated as 'T' spot and which was later identified independently by Crumpler et al [2] and by Fink, Henderson, and Fink [3] as  $\beta$  aminoisobutyric acid ( $\alpha$  methyl  $\beta$  alanine). Crumpler et al [2] found that readily detectable amounts of  $\beta$  aminoisobutyric acid (BAIB) occurred persistently in the urine of approximately 48 per cent of normal British subjects. They suggested that the rate of excretion is controlled by genetic factors. On the other hand, Fink et al [3] in addition to finding a small number of normal individuals who were high excretors, found that a large percentage of cancer patients also were high excretors. Figure 24-1 shows photographs of two-dimensional amino acid chromatograms, one from a high BAIB excretor and the other from a low excretor.

Since these early papers, both the genetic basis for BAIB excretion and the association of BAIB excretion with certain types of disease have been amply confirmed. Harris [4] studied a series of families in London and reported that some individuals consistently excrete large amounts of BAIB (70 to 300 mg per day) and that these persons tend to occur in the same families. Other studies have confirmed this. On the other hand, BAIB excretion has also been reported in association with certain neoplastic diseases, particularly leukemia [3, 5-10] and with tuberculosis [11], march hemoglobinuria [12], liver disease [13], lead poisoning [14],

Research in the author's laboratory is supported in part by Research Grant A-830 from the National Institutes of Health, Public Health Service.

Fig 712 Establishes the metabolic reaction of BAIB as indicated and the

The same enzyme preparation (partially purified) also used  $\beta$ -alanine and  $\gamma$  aminobutyric acid as substrates

### Steric Considerations

Since the  $\alpha$ -carbon of BAIB is asymmetric the question of optical isomerism should be considered in treating the metabolism of BAIB

that BAIB might therefore be a metabolic end product of thymine. Evidence favoring this hypothesis was obtained by feeding large amounts of DNA and RNA to rats. BAIB cannot normally be detected in the urine of rats but on the DNA diet it is excreted. By contrast the RNA diet which does not contain thymine does not cause the excretion of BAIB. The high levels of nucleic acid used in these diets (40 per cent) raised doubts as to the significance of the effect observed but subsequent studies by this same group [21] have confirmed that BAIB can be a metabolite of thymine. Of a variety of pyrimidines injected into rats only thymine and dihydrothymine caused the appearance of BAIB in the urine. Even 5-methylcytosine which has the same carbon skeleton as thymine failed to cause the excretion of BAIB.

Both thymine and dihydrothymine can yield BAIB when incubated with rat liver or kidney slices [22]. Liver is more active in this respect. Dihydrothymine is a much more effective precursor than thymine and thymidine is no better than thymine. No BAIB is formed when these substrates are incubated with a variety of tissues other than liver and kidney. On the other hand liver and kidney from a variety of mammals were shown to form BAIB.

In a subsequent series of papers the Finks and their associates have demonstrated the conversion of thymine by way of dihydrothymine and  $\beta$  uridoisobutyric acid to BAIB as shown in Fig 24.2 [23-24]. An analogous series of reactions was also demonstrated for the conversion of uracil to  $\beta$  alanine [23] and there is evidence that the cleavage of the dihydropyrimidine ring is catalyzed by the same enzyme in both pathways [25]. Canellakis [26] studied these reductive degradation pathways for uracil and thymine and reported that the initial reduction of the pyrimidine ring requires reduced TPN. Grisolia and his associates [27-28] studied the decarbamylation reactions of  $\beta$  ureidopropionic acid and  $\beta$  ureidoisobutyric acid and found that formation of the  $\beta$  amino acids is accompanied by the production of  $\text{NH}_3$  and  $\text{CO}_2$ . However Fink et al [29] using labeled thymine found that the C2 carbon appears in urea. In addition they found that some of the thymine is oxidized at the methyl group indicating an alternate oxidative pathway for thymine degradation. Whether the urea is formed from oxidative degradation or from the carbamate of the reductive pathway is not known. Fink et al [29] were unable to detect 5-methylbarbituric acid which is a breakdown product of thymine in microorganisms.

#### *Relation to Valine*

Coon and his associates have demonstrated the production of BAIB from valine [30-34]. The reactions are indicated in Fig 24.2. Of particular interest is the BAIB-glutamic transaminase reaction studied by Kupiecki and Coon [34]. This conversion of BAIB to methylmalonate semialdehyde provides a means of further catabolism of BAIB regardless of its origin.

mental evidence to support this concept. This mechanism can now be excluded. Crumpler et al [2] reported that the blood levels of BAIB in genetic high excretors were no higher than in the rest of the population and considered this as evidence for a defect in tubular reabsorption. The levels which they found were not reported and it is not clear that they actually detected BAIB in the plasma of any of their subjects. The amount of BAIB circulating in the plasma is far less than other amino acids and paper chromatographic methods which can be used for other amino acids in plasma are inadequate for BAIB either in high or low excretors. Evered [35] was unable to detect BAIB in the plasma by ion exchange chromatography. He computed that the plasma clearance in a high excretor must be at least 85 ml per min indicating little if any tubular reabsorption in these persons. Gartler [36] increased the blood levels of BAIB in nonexcretors artificially by oral administration of thymine and found that the plasma clearance actually exceeded the glomerular filtration rate. Thus it seems likely that BAIB must be classified with those substances which are not reabsorbed at all thereby ruling out a renal mechanism for high excretion both in genetic and nongenetic high excretors.

#### *Rate of Formation of BAIB*

In considering the possibility that increased BAIB excretion results from increased formation from precursors it is necessary to decide which of the two possible pathways—from thymine and from valine—is quantitatively more important. The evidence is meager but favors the thymine pathway. Awapara and Shullenberger [9] found that administration of 1 gm thymine to a variety of patients suffering from neoplastic diseases results in a manyfold increase in BAIB excretion. Similarly Gartler [37] found that ingestion of thymidine, thymine, dihydrothymine or  $\beta$  ureidoisobutyric acid by normal high and low excretors caused increased excretion of BAIB. On the other hand, the oral administration of 500 mg valine to a genetic high excretor and to a low excretor did not result in an increase of BAIB in the urine [37]. This amount of valine is much less than the amount of other amino acids used in tolerance loads and possibly is inadequate to test the ability of valine to serve as a precursor of BAIB. Awapara and Shullenberger [9] also found an increase in BAIB excretion in many of their patients after administration of nitrogen mustard. They interpret this as a consequence of the release of thymine from tissue and suggest that excretion of BAIB may be a useful index of the extent of tissue destruction.

This rate of excretion provides an explanation for the association of high BAIB excretion with certain disease involving increased tissue destruction (e.g. leukemia, march hemoglobinuria). It was early reported that the rate of excretion varied with the clinical state of the patient in

Unfortunately, this has been largely ignored. BAIB from the urine of genetic excretors is levorotatory [2] but this in itself does not indicate which pathway is responsible for the production of excessive amounts of BAIB. Complicating this picture is the observation by Fink, Henderson and Fink [21] that only 15 per cent of a racemic mixture of BAIB injected intraperitoneally into rats is recovered in the urine. This would suggest that both forms can be metabolized. Since the BAIB glutamic transaminase appears to be insensitive to the methyl group reacting either with  $\beta$  alanine or with  $\alpha$  methyl  $\beta$  alanine (BAIB) it is quite possible that it is also insensitive to the steric configuration of the  $\alpha$ -carbon. In the case of valine catabolism and undoubtedly in the case of thymine catabolism only one isomer would be formed in vivo.

#### *Relation to Other Imino Acids*

Although BAIB conforms chemically to the definition of an amino acid it should not be grouped metabolically with the other amino acids. It has never been isolated from a protein nor is it known to participate in peptide bond formation. As will be discussed later it probably does not compete with other amino acids in transport reactions. The amino nitrogen does enter the nitrogen pool of the amino acids by means of the transaminase reaction.

### CAUSES OF EXCESS BAIB EXCRETION

The nature of the metabolic defect which results in BAIB excretion has not been established either in genetic excretors or in persons suffering from various diseases. Indeed there is no a priori reason for supposing that the cause is the same in the two cases. On the basis of the known metabolic reactions of BAIB it is possible to suggest several mechanisms by which BAIB excretion might be increased. It should be kept in mind that there is virtually no information concerning the quantitative importance of the pathways which have been established nor for that matter is it often known which direction predominates in these frequently reversible reactions.

An increased excretion of a metabolite has one of three causes (1) increased formation of that metabolite from its precursors (usually because some alternate pathway of the precursor is blocked), (2) decreased capacity to metabolize the product with the result that the blood levels increase and the substance appears in the urine (3) decreased ability to reabsorb the metabolite from the glomerular filtrate.

#### *Role of Renal Mechanisms*

A renal mechanism has frequently been postulated to account for  $\beta$  aminoisobutyricaciduria but there has never actually been experi-

In the absence of additional experimental evidence it is obviously impossible to decide which of the two pathways from thymine or valine is quantitatively important in the excretion of BAIB. The significant evidence will most probably come from tracer studies rather than from loading experiments in which unphysiologic levels of metabolites are achieved. A point which must also be considered is that in conditions of excessive tissue destruction BAIB excretion occurs in persons who are not genetic excretors. This implies that the ability to metabolize BAIB is limited in such persons also but at a level which permits them to handle normal turnover without appreciable excretion of BAIB. Such a delicate balance is unusual but certainly not impossible.

## GENETICS OF BAIB EXCRETION

### *Detection Methods and the Problem of Classification*

It is impossible to discuss the genetics of BAIB excretion without referring to methods of assay. BAIB was discovered by means of paper chromatography which has remained the principal means of detection. Ion-exchange methods as applied by Evered [31] are the most accurate available at present but genetic studies depend upon the assay of large numbers of samples and the ion-exchange methods are very time consuming. Of necessity the method of choice has been paper chromatography in spite of the relatively large error inherent in its use as a quantitative tool. Furthermore there are several ninhydrin reacting substances which occasionally appear in small quantities in positions on the chromatogram very close to BAIB and it is not always possible on a single chromatogram to distinguish these substances. For these reasons the trace amounts of BAIB frequently reported are apt to reflect substances other than BAIB.

The difficulties imposed by analytic error are apparent when one attempts to assign each individual to a particular category of excretion. In the previous discussions the terms high and low excretor have been used as if the distribution of excretion rates were discontinuous. It would indeed be convenient if individuals could be assigned to nonoverlapping categories since conventional Mendelian analysis is based on attributes rather than on continuous variables. The evidence on this point is contradictory. Some find evidence of bimodality [46] while others find no evidence for bimodality [43]. In populations where the frequency of high excretors is low a very large population sample would be required in order to demonstrate a significant separation between the two groups. However even in populations where the frequency of high excretors is high the evidence for a clear separation between high and low excretors is not convincing. Cartler [37] using a paper electrophoretic technique for estimating BAIB has obtained results which he considers to be

contrast with the relatively constant rate of excretion of normal high excretors [3]. High BAIB excretion is frequently observed in hospitalized patients particularly in small children suffering from obscure metabolic disorders [38]. In the absence of other family information it is probably best to consider these patients as having excessive tissue destruction or at least altered DNA metabolism.

### *Metabolic Disposal of BAIB*

There is certainly no reason to suppose that genetic high excretors have increased tissue destruction. It is conceivable that their DNA metabolism may differ from that of low excretors but Gartler [36, 37] has provided evidence that the difference is in the handling of metabolites subsequent to the reduction of thymine. This is most clearly indicated by the results of oral and intravenous administration of DL-BAIB. Low excretors retain most of the BAIB while high excretors dispose of it in the urine. Since the conversion of  $\beta$  ureidoisobutyric acid to BAIB is essentially irreversible there is no reason to implicate reactions of the thymine pathway prior to the actual formation of BAIB.

It seems necessary to postulate a block in the conversion of BAIB to methylmalonate semialdehyde or in the further metabolism of the latter to propionate etc. If the transaminase reaction is blocked then the catabolism of valine should have little influence on the excretion of BAIB. On the other hand if the block occurs subsequent to methylmalonate semialdehyde and assuming this pathway to be the principal means of valine breakdown, then valine should also contribute to the BAIB excreted.

It is informative to consider the quantities of the various possible precursors which would be required to account for the urinary BAIB in a high excretor. If an excretion rate of 200 mg BAIB per day is assumed as a reasonable value for a high excretor then 240 mg thymine, 470 mg thymidine, 1.04 gm DNA or 227 mg valine would have to be converted with 100 per cent efficiency to urinary BAIB to account for this rate. If the DNA is considered to represent tissue breakdown then approximately 400 to 800 gm fresh tissue would have to be destroyed per day to produce this much DNA (assuming concentrations of 25 to 50  $\mu$ g DNA phosphorus per 100 mg fresh tissue [39]). Such a turnover rate perhaps is not unreasonable [40]. It is quite possible that even if thymine is responsible for all the BAIB produced it does not all come from completed DNA. Valine is an essential amino acid and arises entirely from the diet. The average daily per capita consumption of valine is about 5 gm [41] of which only about 10 per cent is needed to maintain positive nitrogen balance [42]. Thus a diversion of about 5 per cent of the valine into BAIB would account for the amount of BAIB excreted even in high excretors.

amounts of BAIB behaved as a recessive trait. The only mating of high excretor with high excretor produced three high-excretor offspring.

A subsequent study of an Italian population by Calchi Novati et al [45] using the same procedures as those of Harris revealed a frequency of 40 high excretors in a population of 711 individuals over 4 years of age. Again the analysis of family material indicated consistency with the hypothesis that high excretors are homozygous for a recessive gene. The only mating of high excretor with high excretor produced a single high excretor offspring.

Gartler [47] studied a series of New York families using 30 mg per gm creatinine as the dividing line. There were no matings of high excretor with high excretor but the distribution of offspring types in the other matings was consistent with the inheritance of high excretion as a recessive trait.

Grouchy and Sutton [48] studied the inheritance of BAIB excretion in 17 families of Chinese or Japanese extraction. This population is particularly useful since the frequency of high excretors is very much higher in it than in Caucasian populations (Fig 24.2). In the absence of evidence for a distinct antimode statistical techniques were applied which are valid for multigenic inheritance. These showed a high correlation among siblings and between offspring and parents confirming the essentially genetic character of this trait. Although neither the type of segregation within families nor the type of progeny produced by the various matings was entirely compatible with a simple two-allele hypothesis the evidence did not exclude the possibility that a major portion of the genetic variation could be accounted for by a simple two-allele Mendelian system.

Gartler, Firschein and Kraus [49] reported a series of family studies on a Black Carib population which has a high frequency of BAIB excretors. They chose as their dividing line the value

$$\log (\text{O.D. BAIB} / \text{O.D. glycine}) = 1.40$$

where O.D. = the optical density of the amino acid spots measured on paper chromatograms.

The value 1.40 is the point at which an antimode occurred in this population. The results again were in general agreement with the hypothesis that high excretion results from homozygosity for a recessive gene. In this instance there were 5 matings of high excretor with high excretor producing 24 high-excretor offspring and 2 low-excretor offspring. The latter 2 low-excretor offspring are inconsistent with the simple 2 allele system but the true family relationships may not have been ascertained.

In summarizing the foregoing genetic studies perhaps the best conclusion is that the major variation in BAIB excretion is under the control of a very few genes possibly a single pair of alleles and that high excretion results from homozygosity for a recessive allele. There still appear to be

superior to those obtained by the chromatographic methods. As yet no family studies with this method have been reported.

### *Environment Sex Diet and Age*

Before proper genetic studies can be undertaken it is necessary to evaluate the environmental factors which may alter the trait under study. Experiments have already been described in which the BAIB excretion is altered by ingestion of large amounts of thymine, dihydrothymine or  $\beta$ -ureidorsobutyric acid. Such situations are not likely to arise outside a laboratory, however, and all the other evidence favors the view that diet is ordinarily ineffective in changing the level of BAIB excretion. On the assumption that thymine is the precursor of BAIB one study was carried out by placing two individuals—one a high excretor and the other a low excretor, on a meat free diet for 1 week [38]. Although certain other features of the excretion pattern changed the BAIB excretion remained constant and quite different for each individual. In another study of the excretion of BAIB within families, no correlation was found between husbands and wives but there was a significant correlation between parents and offspring [43]. This is good evidence that BAIB excretion is not readily influenced by usual dietary variations. It seems best to consider that excretion of BAIB is the result of endogenous processes not readily influenced by either quantity or quality of food. Other environmental factors have not been investigated for their influence on BAIB excretion but in view of the individual consistency in excretion rates there is little reason to suppose that such factors play a significant role.

Many metabolites vary considerably with age or sex but in the case of BAIB these too appear to be unimportant. None of the studies in which sex differences were investigated has reported a significant difference [4, 43-47]. For the most part no age differences have been reported [4, 43, 46] although several investigators have found increased levels of BAIB among young children (less than 4 or 5 years of age) [10, 44, 46, 47]. The importance of this increase in young children is not known but it suggests caution in the interpretation genetic or otherwise of the excretion levels of young children.

### *Genetic Control*

The first study of the genetic control of BAIB excretion was that of Harris [4] in England. He selected as his dividing line between high and low excretors the amount of BAIB which reacted on paper with ninhydrin to give a spot equal in intensity to the alanine spot of the same urine sample. This amount was estimated to be about 70 mg per gm creatinine. Of the 345 persons examined 33 (9.6 per cent) were high excretors by this criterion. In the family studies the excretion of large

amounts of BAIB behaved as a recessive trait. The only mating of high excretor with high excretor produced three high-excretor offspring.

A subsequent study of an Italian population by Calchi Novati et al [45] using the same procedures as those of Harris revealed a frequency of 40 high excretors in a population of 711 individuals over 4 years of age. Again the analysis of family material indicated consistency with the hypothesis that high excretors are homozygous for a recessive gene. The only mating of high excretor with high excretor produced a single high excretor offspring.

Gartler [47] studied a series of New York families using 30 mg per gm creatinine as the dividing line. There were no matings of high excretor with high excretor but the distribution of offspring types in the other matings was consistent with the inheritance of high excretion as a recessive trait.

Grouchy and Sutton [48] studied the inheritance of BAIB excretion in 17 families of Chinese or Japanese extraction. This population is particularly useful since the frequency of high excretors is very much higher in it than in Caucasian populations (Fig 24.2). In the absence of evidence for a distinct antimode statistical techniques were applied which are valid for multigenic inheritance. These showed a high correlation among siblings and between offspring and parents confirming the essentially genetic character of this trait. Although neither the type of segregation within families nor the type of progeny produced by the various matings was entirely compatible with a simple two-allele hypothesis the evidence did not exclude the possibility that a major portion of the genetic variation could be accounted for by a simple two-allele Mendelian system.

Gartler, Firschein and Kraus [49] reported a series of family studies on a Black Caribbean population which has a high frequency of BAIB excretors. They chose as their dividing line the value

$$\log (\text{O.D. BAIB} / \text{O.D. glycine}) = 1.40$$

where O.D. = the optical density of the amino acid spots measured on paper chromatograms.

The value 1.40 is the point at which an antimode occurred in this population. The results again were in general agreement with the hypothesis that high excretion results from homozygosity for a recessive gene. In this instance there were 5 matings of high excretor with high excretor producing 21 high-excretor offspring and 2 low-excretor offspring. The latter 2 low-excretor offspring are inconsistent with the simple 2 allele system but the true family relationships may not have been ascertained.

In summarizing the foregoing genetic studies perhaps the best conclusion is that the major variation in BAIB excretion is under the control of a very few genes, possibly a single pair of alleles, and that high excretion results from homozygosity for a recessive allele. There still appear to be

other factors either genetic or nongenetic or both, which can influence the amount of BAIB excreted. As new assay techniques become available and the experimental error can be reduced the nature of the genetic factors should also become much clearer.

### RACIAL VARIATION IN BAIB EXCRETION

As with many other inherited traits the frequency of the genes controlling BAIB excretion varies considerably in different populations. This

Fig. 24-3. Distribution of excretion rates of BAIB in various populations. References are given in Table 24-1.

was recognized first during the comparison of the amino acid excretion patterns of a small group of Chinese with that of Americans of European extraction [48]. Instead of the rare high excretor found among Europeans the Chinese were found to have a very high frequency of high excretors.

This difference among populations has been confirmed and extended and the results of some of the studies are summarized in Fig 24-3. Another means of expressing these differences is in the proportion of individuals whose level of excretion is greater than some value. In Table 24-1 are shown the results expressed in this manner with studies of some additional populations whose published values were not expressed in a way which permitted their inclusion in Fig 24-3. It is apparent that the highest excretors occur among the Orientals and among the American Indians with intermediate values for Negroes. Allison, Blumberg, and

TABLE 24-1 FREQUENCIES OF INDIVIDUALS EXCRETING BAIB AT LEVELS GREATER THAN 30 MG PER GM CREATININE IN VARIOUS POPULATIONS

| Population        | Frequency of excretors | % of persons | Reference |

| New York          | 0.15                   | 38           | [10]      |
| Chinese           | 0.45                   | 31           | [38]      |
| Japanese          | 0.415                  | 41           | [33]      |
| Thai              | 0.46                   | 11           | [38]      |
| Ap chos (Arizona) | 0.416                  | 111          | [10]      |

Gartler [40] have also reported high values for the Athabaskan-speaking Indians of Alaska but found that the Alaskan Eskimos are intermediate between the Indians and whites.

The existence of such genetic polymorphism among all the populations studied can be interpreted as indicating a very early origin of the (two) alleles with the heterozygous individuals possibly enjoying some selective advantage over their homozygous neighbors. The possibility of independent mutations at this locus cannot be excluded, of course. The nature of the selective factors is unknown.

## SUMMARY

1.  $\beta$ -Aminoisobutyric acid (BAIB) occurs in the urine of some persons in amounts up to 200 to 300 mg per day either as an inherited trait or as a consequence of some disease process.

2. Enzymes are present in animal tissues which form BAIB from thymine and from valine but present evidence is not conclusive as to the

actual origin of urinary BAIB. In some disease states the increased BAIB excretion probably reflects excessive tissue destruction with concomitant high DNA catabolism.

3. BAIB is not reabsorbed by the renal tubules either in low or high excretors of BAIB. The failure of genetic low excretors to excrete ingested BAIB while high excretors do excrete ingested BAIB is evidence that a block exists in the further metabolism of BAIB. This may be either in the transamination to methylmalonate semialdehyde or in subsequent steps.

4. The evidence for dimorphism in the excretion rates of BAIB is not clear cut although recently developed techniques may resolve some of the earlier reported discrepancies. Nevertheless the principal genetic variation seems to be largely explained on the basis of a two-allele system with high excretors being homozygous for a recessive gene. There still remains variation either genetic or nongenetic which is not explained by such a system.

5. Sex and diet do not appear to influence the excretion of BAIB. Very young children are reported to be high excretors more often than adults but age does not appear to affect the excretion rate among persons over 5 years of age. The frequencies of persons who excrete large amounts of BAIB vary with the population under study. The lowest frequencies are found in white populations and the highest in Mongolians and American Indians with Negroes intermediate.

## Part Seven

### Diseases Primarily Manifest as Abnormalities in Metal Metabolism

---

## Chapter 25

### Wilson's Disease\*

---

*Alexander G. Bearn*

It is quite certain that if this book had been conceived 25 years ago it would have been comfortably slimmer and would not have included a chapter on Wilson's disease. The view would have been almost unanimously held that the disease could not be considered either inherited or metabolic. Although during the past 25 years the nature of the disease has become greatly clarified, the basic metabolic defect underlying its cause remains obscure.

Wilson's disease (hepatolenticular degeneration) is a relatively rare disease occurring predominantly in young people. It is characterized by cirrhosis of the liver and degenerative changes in the brain, particularly in the basal ganglia. The greenish brown Kayser-Fleischer rings seen in the periphery of the cornea are pathognomonic of Wilson's disease. Genetic studies have revealed that the condition is inherited in an autosomal recessive fashion.

#### CLINICAL FEATURES

In 1912 Kinross Wilson published his monograph entitled "Progressive Lenticular Degeneration: A Familial Nervous Disease Associated with Cirrhosis of the Liver." [1] While still a young man Wilson had under his care a patient who died after a long illness characterized by muscular rigidity, tremor, and forced grimacing. Cirrhosis of the liver and gross degenerative changes in the lenticular nucleus of the brain were found at autopsy. On searching the literature, Wilson found other cases which were clinically similar. Six years earlier Cowers, in a paper entitled "Tetynoid Chorea Associated with Cirrhosis of the Liver," described

The author is indebted to Professor L. S. Penrose for his helpful discussions concerning the interpretation of the genetic data and to Professor Charles H. Rodeck and Dr. James L. Cerman III for their assistance in the preparation of the manuscript.

two patients whose symptoms were similar to those of Wilson's patient [2]. A review of the literature at that time disclosed that the disease had been seen sporadically in the past but had escaped systematic study. The first case of recognized Wilson's disease was probably described by Frerichs in his classic monograph on liver disease in 1861 [3]. The patient, a young boy, suffered from severe liver disease associated with violent tremors and convulsions and died at the age of 10. An autopsy revealed cirrhosis of the liver. The age of the patient and the nature of his symptoms make the diagnosis of Wilson's disease although unproved highly likely.

The clinical characteristics of Wilson's disease may be so unique that in many instances the diagnosis is not in doubt. Unfortunately the "typical case" is becoming less frequent as understanding of the varied clinical manifestations of the disease increases.

### *Lenticular Degeneration*

This form of the disease is the one seen by Wilson and overemphasized by subsequent observers. In fact, classic lenticular degeneration is a severe but relatively uncommon form of the disease which occurs predominantly in young adults. Spasticity, rigidity, dysarthria, and dysphagia are the common presenting symptoms. Tremor is usually less pronounced and clinical evidence of hepatic disease is minimal or absent although as in all varieties of Wilson's disease pathologic evidence of cirrhosis is almost invariable. Acute unexplained febrile episodes were recognized by Wilson in some of his patients and may usher in the terminal phase of the disease.

### *Pseudosclerosis*

Unnecessary and frequently acrimonious nosologic debate obscured the existence of this variety of hepatolenticular degeneration during the early part of this century. It is now clear that what has been known as pseudosclerosis of Westphal [4] is a variant of Wilson's disease in which tremor is usually the major disabling symptom, while rigidity and spasticity are less marked. Symptoms referable to hepatic dysfunction are uncommon but pathologic evidence of cirrhosis can invariably be found and impairment of Bromsulfalein excretion can frequently be demonstrated [5]. Other biochemical evidence of disturbed liver function is usually slight.

### *Kayser Fleischer Ring*

Despite the brilliance of Wilson's clinical acumen the only pathognomonic sign of the disease escaped him. Ten years before the publication of Wilson's paper Kayser had observed a greenish yellow ring at the limbus of the cornea in a patient diagnosed as having multiple sclerosis. A year later Fleischer reported a corneal ring as an integral part of a

neurologic disease associated with cirrhosis of the liver. In a series of papers [6-8] Fleischer proposed the concept that the changes in the eye, brain, and liver were all due to a common metabolic cause. The Kayser-Fleischer ring is still rightly regarded as the single most important diagnostic sign of the disease. The ring is not always complete and is usually most marked at the superior and inferior aspects of the cornea. Although with experience most Kayser-Fleischer rings can be seen by inspection of the cornea, its presence can be definitely excluded only by a slit lamp examination. In a very few patients careful examination of the eye will reveal a *Sonnenblumenkatarakt*. Similar cataracts are known to follow the intraocular localization of a foreign body containing copper.

### *Cirrhosis of the Liver*

The hepatic form of Wilson's disease, in which there is evidence of liver abnormality with minor or absent neurologic signs, has been recognized as a clinical variant for many years [9]. Its frequency and significance have recently become increasingly appreciated [10]. In a series of 32 cases collected at the Rockefeller Institute between 1951 and 1958, 8 (25 per cent) could be classified as belonging to this group. It seems likely that a significant but unknown proportion of patients with juvenile cirrhosis actually suffer from Wilson's disease. No patient with juvenile cirrhosis has been satisfactorily examined unless the presence of Kayser-Fleischer rings has been diligently sought and the biochemical tests necessary for the diagnosis of Wilson's disease have been performed. The cirrhosis is similar pathologically to that seen in the pseudosclerotic variety of the disease but is generally more severe. Signs of portal hypertension can frequently be demonstrated. In some patients with Wilson's disease the presenting symptom is massive hemorrhage due to rupture of esophageal varices. Hepatic coma may usher in the terminal phase. Ascites rarely occurs except in the later stages of hepatic decompensation.

### *Other Clinical Variants*

A sizable proportion of patients with Wilson's disease may present with symptoms suggesting schizophrenia; others may develop less pronounced abnormalities in behavior or personality. Tragic ignorance of this form of the disease has resulted in needless shock therapy and unnecessary detention in psychiatric hospitals.

Occasionally patients may develop epileptic seizures, usually of the Jacksonian type. Hemiplegia is not so rare as is commonly supposed. A curious comatose state may persist for several weeks and does not necessarily herald an immediate fatal outcome.

### *Etiology*

Two hypotheses are current concerning the probable pathogenetic mechanism of Wilson's disease. The first and presently more favored

hypothesis regards the disease as a primary disturbance in copper metabolism. The second ascribes the disease to a more generalized disorder of tissue protein metabolism. Neither of these two hypotheses is entirely satisfactory and both philosophy and common sense suggest that the final view will incorporate features of both. For purposes of clarity in exposition these two hypotheses will be dealt with separately and the defects of each emphasized.

## NORMAL METABOLISM OF COPPER

Copper is an ubiquitous element. Under normal circumstances the average individual consumes between 2.5 and 5.0 mg copper per day. Foods with high copper content include liver, shellfish, nuts, and chocolate. Cow's milk usually contains only a small amount of copper and has been used successfully to induce copper deficiency in certain animals. In most foodstuffs copper is bound principally to proteins and amino acids. Copper may be present in significant quantities in drinking water particularly if the pipes are copper lined.

### *Ceruloplasmin Copper*

Copper in the serum is bound to the plasma proteins. Approximately 98 per cent of the circulating serum copper in man is bound to an  $\alpha_2$ -globulin. Purification of the  $\alpha_2$ -globulin fraction has resulted in the isolation of a copper protein which, because of its blue color, is called ceruloplasmin.

Ceruloplasmin has a molecular weight of about 151,000 and contains eight copper atoms per molecule [11, 12]. Holmberg and Laurell [13, 14] have described some of its properties. The protein is an oxidase with many properties in common with plant laccases. Among the variety of compounds toward which it exhibits oxidase activity are biologically important substances such as epinephrine and serotonin, as well as synthetic substrates [15]. The greatest oxidase activity has been demonstrated using as substrate the dye, paraphenylenediamine. The enzymatic activity may be accelerated by low concentrations of a variety of monovalent anions including chloride, bromide, and acetate. Higher concentrations of these may inhibit. Some polyvalent ions, phosphate and citrate, for example, may inhibit the enzymatic reaction and cause a prolonged induction period. Whether ceruloplasmin exhibits enzyme function *in vivo* is uncertain.

Procedures designed to dissociate copper from ceruloplasmin have resulted in loss of enzymatic activity. It has been demonstrated by the use of  $\text{Cu}^{64}$  that under appropriate conditions half of the eight copper atoms of each ceruloplasmin molecule can exchange with ionic copper [16]. This will take place only if the protein first is reduced to its colorless form. Ceruloplasmin *in vivo* may, under certain circumstances, exchange

its copper with copper absorbed from the gastrointestinal tract [17]. If this mechanism can be demonstrated to occur under physiologic conditions ceruloplasmin would perform a role in copper transport similar to that of transferrin in iron transport. It is also possible that ceruloplasmin is a storage protein. Since a gross deficit of ceruloplasmin has been demonstrated in a healthy carrier of the abnormal gene of hepatolenticular degeneration it is unlikely that its enzymatic function is vital to the organism. The relationship of ceruloplasmin to mental disease [18] remains too speculative for further comment. It is clear that the relationship, if any, is both tenuous and indirect [19].

**Ceruloplasmin Determination** Serum ceruloplasmin can be measured in a variety of ways. Holmberg and Laurell originally demonstrated a positive correlation between the copper content of the serum and its oxidase activity using paraphenylenediamine as a substrate. The oxidase activity can be measured directly in a Warburg apparatus and recorded in terms of micromoles of  $O_2$  uptake per milliliter per hour. Alternatively the oxidase activity can be measured colorimetrically. Ravin has outlined a rapid method for ceruloplasmin determination using this principle [20]. Other methods for estimating this protein depend upon the blue color. Measurement of the optical density before and after destruction of the blue color by ascorbic acid or cyanide is an index of the concentration of ceruloplasmin [21]. Ceruloplasmin can also be measured immunologically [22]. This of course is dependent upon the availability of a pure preparation of ceruloplasmin which can be used as an antigen. In 1958 Broman [23] reported the existence of multiple ceruloplasmins in normal plasma with similar enzymatic properties. The main component accounts for approximately 80 per cent of the total ceruloplasmin. The heterogeneity of ceruloplasmin observed by Broman and recently confirmed by Saks Kortrik [23a] may have important implications in the understanding of the mechanism of gene action in Wilson's disease.

#### *Nonceruloplasmin Copper*

It can be shown by salt fractionation and more precisely by electrophoretic techniques that the nonceruloplasmin copper is bound to serum albumin [24]. The physical and chemical characteristics of the copper albumin complex have been extensively studied [25]. In general it may be stated that the main copper binding sites of the albumin molecule are the imidazole groups but some weaker binding also occurs at the carboxyl group. The extent of the binding depends on the pH and the competitive effect of other anions in solution. Heating to approximately 100 C does not disturb the ability of protein to form complexes with copper in contrast to its effect on protein anion complexes. The essential requirements for binding appear to be the presence of appropriate residues and favorable electrostatic conditions of the molecule.

hypothesis regards the disease as a primary disturbance in copper metabolism. The second ascribes the disease to a more generalized disorder of tissue protein metabolism. Neither of these two hypotheses is entirely satisfactory, and both philosophy and common sense suggest that the final view will incorporate features of both. For purposes of clarity in exposition these two hypotheses will be dealt with separately and the defects of each emphasized.

## NORMAL METABOLISM OF COPPER

Copper is an ubiquitous element. Under normal circumstances the average individual consumes between 2.5 and 5.0 mg copper per day. Foods with high copper content include liver, shellfish, nuts, and chocolate. Cow's milk usually contains only a small amount of copper and has been used successfully to induce copper deficiency in certain animals. In most foodstuffs copper is bound principally to proteins and amino acids. Copper may be present in significant quantities in drinking water, particularly if the pipes are copper lined.

### *Ceruloplasmin Copper*

Copper in the serum is bound to the plasma proteins. Approximately 98 per cent of the circulating serum copper in man is bound to an  $\alpha_2$ -globulin. Purification of the  $\alpha_2$ -globulin fraction has resulted in the isolation of a copper protein which, because of its blue color, is called ceruloplasmin.

Ceruloplasmin has a molecular weight of about 151,000 and contains eight copper atoms per molecule [11, 12]. Holmberg and Laurell [13, 14] have described some of its properties. The protein is an oxidase with many properties in common with plant laccases. Among the variety of compounds toward which it exhibits oxidase activity are biologically important substances such as epinephrine and serotonin, as well as synthetic substrates [15]. The greatest oxidase activity has been demonstrated using as substrate the dye paraphenylenediamine. The enzymatic activity may be accelerated by low concentrations of a variety of monovalent anions including chloride, bromide, and acetate; higher concentrations of these may inhibit. Some polyvalent ions, phosphate and citrate, for example, may inhibit the enzymatic reaction and cause a prolonged induction period. Whether ceruloplasmin exhibits enzyme function *in vivo* is uncertain.

Procedures designed to dissociate copper from ceruloplasmin have resulted in loss of enzymatic activity. It has been demonstrated by the use of  $\text{Cu}^{2+}$  that under appropriate conditions half of the eight copper atoms of each ceruloplasmin molecule can exchange with ionic copper [16]. This will take place only if the protein first is reduced to its colorless form. Ceruloplasmin *in vivo* may, under certain circumstances, exchange

copper [30] The liver, central nervous system and kidney have the highest copper content (Table 25-2) The muscles and bones because of their total mass contain over 50 per cent of the total body copper Curiously, the fetal liver contains about ten times the amount of copper found in an adult liver The copper content of the liver of a child reaches the level found in a young adult by the age of 10

Several copper proteins have been isolated from the liver Mann and Keilin isolated a colorless copper protein from the liver of the ox [31]

TABLE 25-2 MEAN COPPER CONTENT OF VARIOUS ORGANS IN NORMAL SUBJECTS AND PATIENTS WITH WILSON'S DISEASE

| Organ         | Normal subjects | Patients with Wilson's disease |
|---------------|-----------------|--------------------------------|
| Liver         | 0.5             | 10.0 (5.0-20.0)                |
| Kidney        | 0.3             | 1.0 (0.5-2.0)                  |
| Basal ganglia | 0.6             | 3.0 (2.0-8.0)                  |
| Cortex        |                 |                                |
| White         | 0.5             | 5.0 (3.0-10.0)                 |
| Gray          | 0.4             | 6.0 (4.0-8.0)                  |

All values expressed as mg per 100 gm wet weight

This protein was not crystallized and accounted for only a part of the total copper present in the liver Mohamed and Greenberg isolated an apparently crystalline copper protein from horse liver The protein was blue contained 0.30 to 0.40 per cent copper and had an estimated molecular weight of 30,000 to 40,000 This protein has been named hepatocuprein unlike ceruloplasmin it does not exhibit any oxidase activity [32]

The nature of the copper proteins of normal brain (cerebrocuprein) has been extensively studied by Huntington Porter [33-35] Thus far three copper-containing fractions of normal brain have been isolated and their properties described Fraction I is extracted with acetate buffer at pH 4.5 fraction II is obtained by extraction of the residue from fraction I with water at pH 3.5 at very low ionic strength the final residue fraction is designated fraction III From fraction I has been isolated a green copper-containing protein named cerebrocuprein I This protein contains 0.2 to 0.3 per cent copper and appears 60 per cent homogeneous by ultracentrifugal and electrophoretic techniques It has a molecular weight of approximately 30,000 to 40,000 Cerebrocuprein I exhibits two rather singular properties Copper is not released from cerebrocuprein I by dialysis at pH 3.9 and approximately 10 per cent of its copper reacts directly with diethyldithiocarbamate It is not yet known with certainty whether this direct reacting moiety of normal cerebrocuprein I is of physiological importance or whether it is an artifact Copper is widely di-

Ionic copper reacts with diethyldithiocarbamate to form a characteristic yellow color. Copper in ceruloplasmin will not react with this reagent unless the copper is first released from the ceruloplasmin. The copper which is bound to albumin reacts directly with this reagent and permits the detection and quantitation of the albumin bound copper. This fraction has been designated the "direct reacting copper" by Cartwright and his associates [26]. It seems probable that although the total amount of albumin copper does not normally greatly exceed 5 per cent of the total serum copper, it performs the essential task of transporting copper from the intestinal tract to the various tissues of the body and is metabolically the most active fraction of the serum copper.

### *Erythrocuprein*

Copper is a normal component of adult red cells where its function is unknown. At least 80 per cent of the copper in erythrocytes is present

TABLE 25-1 A COMPARISON OF THE PHYSICAL AND CHEMICAL PROPERTIES OF ERYTHROCUPREIN AND CERULOPLASMIN

| Property                     | Erythrocuprein          | Ceruloplasmin   |
|------------------------------|-------------------------|-----------------|

SOURCE: Adapted from C. I. Cartwright et al. See references [27-29].

in the form of erythrocuprein, a nearly colorless protein recently isolated from human red cells by Cartwright and his colleagues [27-29]. A comparison of some of the physical properties of erythrocuprein and ceruloplasmin is shown in Table 25-1.

In copper deficient animals a severe anemia develops which is morphologically similar to the anemia of iron deficiency. The erythrocytes of the copper deficient pig have a shortened survival time but when transfused into a normal pig they have approximately the normal life span. Erythrocytes transfused from a normal to a copper deficient pig also survive normally. Such evidence suggests that the shortened survival time of erythrocytes in copper-deficient animals is not due to an extracorporeal abnormality. Rapid exchange can take place between the serum copper and the red cell copper both *in vivo* and *in vitro* [27].

### *Tissue Copper*

It is hardly surprising that copper is widely distributed in all body tissues. The body of a normal adult contains approximately 150 mg

1915 when Glazebrook reported a patient with Wilson's disease whose liver and brain at autopsy revealed an increased copper concentration and whose serum copper was considered elevated [41] (In view of subsequent findings the increased serum copper reported may possibly have been in error) In all events the observations of Glazebrook proved to have catalytic consequences and a bewildering spate of papers on copper metabolism ensued The next major event was the chance finding by Mandelbrote and his coworkers [42] that a patient suffering from Wilson's disease excreted an increased quantity of copper in the urine Numerous observers have now amply confirmed both the increased tissue copper and the high urinary copper excretion Considerably more disagreement has developed in regard to the serum copper concentration in Wilson's disease Although initial observers reported both normal and elevated levels it was subsequently shown that the levels were almost invariably decreased [43] Recently the wheel has turned full circle and several patients with unequivocal Wilson's disease have now been observed in whom the serum copper is unquestionably normal [44-45] whether this is normal ceruloplasmin will be discussed more fully later

### *Serum Ceruloplasmin*

Almost simultaneously in different laboratories and with different methods diminished ceruloplasmin levels were found in patients with Wilson's disease The first method used was based on its enzymatic activity [43] as described by Holmberg and Laurell and the second more elegant method based on quantitative immunologic procedures in which antiserum had been prepared against crystalline ceruloplasmin [22] A colorimetric procedure based on its oxidase properties has also been employed

Although the majority of patients with Wilson's disease have a diminished serum ceruloplasmin level the degree of depression varies widely In some individuals essentially no ceruloplasmin can be detected In others the level is depressed to about 25 per cent of its normal value (Fig 23-1) Several subjects with Wilson's disease have been reported in whom the ceruloplasmin levels were within the normal range Whether the ceruloplasmin present is precisely the same molecule which exists in normal subjects requires further study

In some patients with Wilson's disease as in normal subjects an increase in the ceruloplasmin concentration can be achieved by the administration of estrogens (Fig 23-2) [46] This effect is most marked in those in whom the ceruloplasmin level is least depressed As might be anticipated in those patients in whom little or no ceruloplasmin can be detected no measurable increase in the ceruloplasmin level occurs In some patients a pronounced cupuremia may follow the administration of estrogens [47a]

tributed in all parts of the brain. The selective deposition of copper in the basal ganglia has been unduly stressed. Vogel [35a] has recently demonstrated an increased copper content of the brain of goldfish when reared in an environment in which the ionic copper is experimentally increased.

Ceruloplasmin in trace amounts has been found in the liver and the kidney [36]. The physiologic significance of this observation if any is uncertain.

### *Secretions*

Copper is present in trace amounts in most of the body fluids including saliva, milk, tears, and sweat. The urine in the absence of significant proteinuria contains only small amounts of copper; the daily 24 hr urine excretion rarely exceeding 0.1 mg per day. The form in which copper is present in normal urine is uncertain; only part is freely dialyzable.

### *Physiologic Variations in Copper Metabolism*

The significance of the alterations in copper metabolism in Wilson's disease cannot be appreciated unless the normal physiologic variations are understood.

Ceruloplasmin increases under a variety of physiologic conditions. It may be increased in pregnancy, infections, thyrotoxicosis, cancer, and cirrhosis of the liver. It is frequently decreased in the newborn and in sprue, nephrosis, anemia (in infants), and malnutrition (in infants). It is almost invariably decreased in Wilson's disease. The administration of estrogens to normal subjects increases the ceruloplasmin level [37].

## ABNORMALITIES OF COPPER METABOLISM IN WILSON'S DISEASE

### *Historical*

A number of early German workers implicated various heavy metals including copper as possible etiologic agents in Wilson's disease. In 1913, only 2 years after Wilson's classic paper, Rumpel reported an increased silver and copper content of the liver and kidneys of patients who had died from pseudosclerosis [38]. In retrospect, it appears that these patients were almost certainly suffering from unrecognized Wilson's disease. Nine years later, Siemerling and Oloff, on the basis of the similarity of the eye cataracts in Wilson's disease to those following injury from a copper-containing foreign body, made the bold suggestion that copper might be deposited in the liver and brain in this disease as well as in the eye and might be directly responsible for the disease [39].

Because of technical difficulties, the possible role of heavy metals in the etiology of the disease remained confused until 1930, when Haurowitz convincingly demonstrated an increased copper content of the liver and brain [40]. Despite this unequivocal clue, the subject lay dormant until

1945 when Glazebrook reported a patient with Wilson's disease whose liver and brain at autopsy revealed an increased copper concentration and whose serum copper was considered elevated [41] (In view of subsequent findings the increased serum copper reported may possibly have been in error.) In all events the observations of Glazebrook proved to have catalytic consequences and a bewildering spate of papers on copper metabolism ensued. The next major event was the chance finding by Mandelbrote and his coworkers [42] that a patient suffering from Wilson's disease excreted an increased quantity of copper in the urine. Numerous observers have now amply confirmed both the increased tissue copper and the high urinary copper excretion. Considerably more disagreement has developed in regard to the serum copper concentration in Wilson's disease. Although initial observers reported both normal and elevated levels it was subsequently shown that the levels were almost invariably decreased [43]. Recently the wheel has turned full circle and several patients with unequivocal Wilson's disease have now been observed in whom the serum copper is unquestionably normal [44-45] whether this is normal ceruloplasmin will be discussed more fully later.

### *Serum Ceruloplasmin*

Almost simultaneously in different laboratories and with different methods diminished ceruloplasmin levels were found in patients with Wilson's disease. The first method used was based on its enzymatic activity [43] as described by Holmberg and Laurell and the second more elegant method based on quantitative immunologic procedures in which antiserum had been prepared against crystalline ceruloplasmin [22]. A colorimetric procedure based on its oxidase properties has also been employed.

Although the majority of patients with Wilson's disease have a diminished serum ceruloplasmin level the degree of depression varies widely. In some individuals essentially no ceruloplasmin can be detected. In others the level is depressed to about 25 per cent of its normal value (Fig. 25-1). Several sibships with Wilson's disease have been reported in whom the ceruloplasmin levels were within the normal range. Whether the ceruloplasmin present is precisely the same molecule which exists in normal subjects requires further study.

In some patients with Wilson's disease as in normal subjects an increase in the ceruloplasmin concentration can be achieved by the administration of estrogens (Fig. 25-2) [46]. This effect is most marked in those in whom the ceruloplasmin level is least depressed. As might be anticipated in those patients in whom little or no ceruloplasmin can be detected no measurable increase in the ceruloplasmin level occurs. In some patients a pronounced cupurexis may follow the administration of estrogens [46a].

N Normals  
W Wilson's Disease  
C = Cirrhosis

Fig 25-1 Comparison of amounts of serum copper, serum ceruloplasmin, and urinary copper in normal subject, cirrhotic patients, and patients with Wilson's disease. Horizontal lines represent mean values. Note the one patient with Wilson's disease in whom a normal ceruloplasmin level occurred. (Reproduced from A G Bearn [69].)

### Serum Copper

Early in the course of investigations on Wilson's disease it was found that the serum copper level was higher than would have been expected from the ceruloplasmin levels observed. Since there was no evidence that ceruloplasmin in Wilson's disease contained more copper per molecule, it seemed probable that the nonceruloplasmin copper was increased. Observations by Cartwright have now established that the direct reacting copper is elevated in Wilson's disease (Fig 25-3). It is possible

Fig 25.2 Effect of estinyl on the serum ceruloplasmin of a patient with Wilson's disease (Reproduced from J G Beermann [1961] with permission of the Honorary Editor of the Royal Society of Medicine)

Fig 25.3 Note (1) decrease in total serum copper (2) decrease in serum ceruloplasmin (3) increase in directly reacting copper (albumin bound copper) in Wilson's disease

that the increased concentration of the direct reacting copper reflects the mechanism by which excess copper is deposited in the tissue

### *Urinary Copper Excretion*

Although an increased copper excretion is usually considered to be one of the cardinal biochemical abnormalities in Wilson's disease it should be appreciated that a moderate increase in urinary copper excretion can occur in cirrhosis of the liver particularly of the biliary type. Urinary copper excretion estimations are, therefore, unreliable in excluding Wilson's disease as a cause for juvenile cirrhosis. Fortunately this important clinical differential diagnosis can usually be settled by a determination of the level of serum ceruloplasmin (Fig. 25.1).

The extent of the increased urinary copper excretion in Wilson's disease varies considerably. In general those individuals with the shortest duration of clinical disease tend to have the more nearly normal levels, those in whom the disease has been present for a long time may excrete as much as 1.5 mg copper daily. In individual patients it is usually possible to observe a slow but progressive increase in the urinary excretion of copper over a period of years. Thus far no patient with clear clinical evidence of Wilson's disease has been seen in whom the urinary copper excretion was completely normal.

Under standard dietary conditions day-to-day fluctuations in the urinary excretion of copper are relatively slight and are largely independent of the urinary volume and the dietary copper intake [47]. In contrast to the insensitivity of the urinary excretion of copper to a twenty-five fold increase in copper intake a ten fold increase in the dietary protein intake results in an approximately two fold increase in the urinary excretion of copper. In normal subjects trivial and inconstant increases in copper excretion are observed following a similar increase in the protein intake. The increased copper excretion which follows the augmented protein intake is paralleled by the increased amino acid excretion. It is tempting to ascribe in part the increased copper excretion to the capacity of many amino acids to chelate copper. However quantitative considerations compel one to qualify such an interpretation for chelation implies a necessary molar relationship between the quantity of amino acids and the quantity of copper excreted.

### *Tissue Copper*

The intrahepatic distribution of copper in Wilson's disease has been recently studied by Uzman using a histologic method [48]. Rubeanic acid forms a black precipitate with copper possibly because of the formation of the imido internal salt of rubeanic acid. Under neutral or slightly alkaline conditions this reaction has a reported sensitivity of 0.006  $\mu\text{g}$  copper. The original method using rubeanic acid suffered from certain

drawbacks. The modification recently introduced appears more satisfactory although attention to detail is still imperative if reproducible results are to be obtained. A marked variation in the copper content of various liver lobules has been described.

The intracellular distribution of copper can be arbitrarily divided into three stages. At first a fine diffuse distribution of copper is present throughout the cytoplasm of the liver cell. Later copper is concentrated around one pole of the nucleus. In the heavily involved lobules the granular copper deposits near the nucleus are coarse but become finer as the periphery of the cell is approached. Copper is not found in the Kupffer cells of the liver. Examination of the histologic appearance of the liver at various stages of the disease suggests that the copper deposition precedes the cirrhotic process. It seems clear that the liver cells have a particular affinity for copper. Whether this is because of the presence of specific abnormal liver proteins with a high affinity for copper or because of the binding of copper to normal cellular constituents will be discussed in detail later.

In the brain copper is distributed widely. No single area appears exempt. In some instances copper is deposited in large quantities in the cerebral cortex, but usually the basal ganglia bear the brunt of the disease. Although the details of the histologic localization of copper in the brain remain uncertain its presence in glial rather than nerve cells has been reported. The neurons however show deterioration [49].

The Kayser Fleischer ring has been examined for the presence of heavy metals ever since the early studies of Siemerling and Orloff. Recently the histochemical and electron microscopic studies of Uzman have clarified a rather confused subject [50]. It has now been demonstrated by two groups of workers that the copper content of the substantia propria may be increased without causing any cloudiness of the cornea or any noticeable color change. The copper in the substantia propria is alcohol insoluble but easily removed by dilute acids or chelating agents such as Verene. In Descemet's membrane on the other hand the copper is localized as a fine granular deposit arranged in two parallel zones close to the endothelial surface of the membrane. The characteristic brown or gray green color of the Kayser Fleischer ring is not directly due to the deposition of copper in Descemet's membrane. The presence of dense layers of copper depositions separated by intervening clear zones provides an ideal physical system for the scattering and reflection of incident light on the cornea and gives rise to the characteristic appearance of the Kayser Fleischer ring.

#### *Dynamic Aspects of Copper Metabolism*

Thus far this account of the abnormalities of copper metabolism in Wilson's disease has been entirely restricted to the realm of descriptive

biology, it seems appropriate now to consider some of its dynamic aspects. This problem has been clarified by the use of radioactive isotopes. Copper<sup>64</sup> has a half life of only 12.88 hr which limits the time during which studies on man can be performed. However, another isotope of copper, Cu<sup>67</sup>, with a considerably longer half life exists; if it becomes available, it will enable prolonged studies to be performed to supplement the observations obtained using Cu<sup>64</sup>.

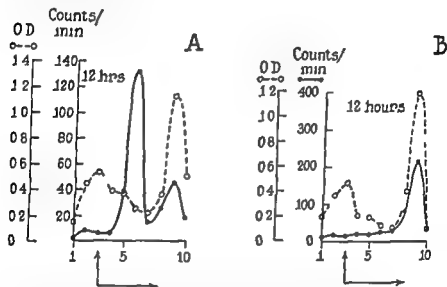

Fig. 25-4. Distribution of radioactive copper in the electrophoretically separated fractions of the serum of control subjects (A) and a patient with Wilson's disease (B) 12 hrs following oral administration of Cu<sup>64</sup>. (Adapted from I. G. Bearn et al. [21].)

A characteristic and reproducible series of curves is obtained after the intravenous administration of radioactive copper to normal subjects [21, 22] (Fig. 25-4). An initial rapid fall in serum labeled copper is followed by a rise. This is succeeded by a slow decline of radioactivity. In patients with Wilson's disease the initial decline of radioactivity is slower than in normal subjects and no secondary rise is observed. Electrophoretic separation of serum and salt fractionation at various intervals after administration of the isotope have shown that immediately following the administration of Cu<sup>64</sup> the radioactivity is bound to serum albumin and no radioactivity is detected in any of the other serum fractions. During the normal secondary rise the radioactivity is associated with the ceruloplasmin and little or no labeled copper is found in association with the albumin. In patients with Wilson's disease as in normal subjects the Cu<sup>64</sup> is first associated with serum albumin but it remains bound to albumin at a time when in normal persons the Cu<sup>64</sup> is associated with ceruloplasmin (Fig. 25-5).

The tentative explanation of these findings is that in both normal subjects and patients with Wilson's disease copper is transported on the serum albumin to various parts of the body. Some copper is transported to the site of ceruloplasmin synthesis where provided the capacity to synthesize ceruloplasmin is normal it becomes incorporated into newly synthesized ceruloplasmin. Since impaired ceruloplasmin synthesis is a usual feature of Wilson's disease the copper transported to the liver is not utilized in this way; it is deposited at various tissue sites and remains

Fig. 23-5 Radioactivity in fractions of plasma produced by addition of rabbit anti-human ceruloplasmin serum. The values on the ordinate refer to counts per minute per milliliter of radio-copper ingested appearing in fractions derived from 1 ml plasma (Reproduced from S. I. Burch et al. [5]).

bound to the albumin in quantities greater than in normal subjects. The copper albumin complex is a relatively loose bond; the copper can easily be dissociated from the protein moiety. The increased quantity of copper in the urine in Wilson's disease is no longer anomalous, for although the total circulating copper is diminished, the copper bound to serum albumin is increased and copper is excreted in the urine. An asymptomatic normal sibling in whom ceruloplasmin was deficient handled intravenous  $\text{Cu}^{64}$  similarly to patients with clinical Wilson's disease [38].

Recently Sass Kortsak has studied the fate of intravenous  $\text{Cu}^{64}$  in a patient with Wilson's disease in whom the ceruloplasmin level was normal [45]. No radioactivity could be demonstrated in association with the ceruloplasmin, and the  $\text{Cu}^{64}$  remained associated with the serum albumin as in those patients with Wilson's disease in whom ceruloplasmin was depressed. Whether this failure of incorporation of  $\text{Cu}^{64}$  into cerulo-

plasma is evidence of a failure to exchange the radioactive copper with the nonradioactive copper or whether as seems more likely, it is due to an alteration in the structure of ceruloplasmin, remains to be determined.

Since the total body copper is increased in Wilson's disease and because the urinary excretion is elevated it is clear that an increased quantity of dietary copper must be absorbed through the intestinal tract. Balance studies have tended to indicate that increased absorption does indeed occur as does a decreased excretion of copper through the intestinal tract. The use of radioactive copper has enabled the increased absorption of copper to be demonstrated clearly [52].

Uptake of  $\text{Cu}^{64}$  by erythrocytes (in erythrocytuprein) of patients with Wilson's disease is similar to that of normal subjects. This emphasizes the rather specific nature of the ceruloplasmin defect in this condition [53]. An explanation for the hemolytic anemia found in some patients with Wilson's disease is not readily deduced from the studies on copper metabolism of the red cell [54].

## RENAL ABNORMALITIES IN WILSON'S DISEASE

In 1948 Uzman and Denny Brown reported an increased amino aciduria in patients with Wilson's disease [55]. Dent in the previous year had also observed an increased excretion of amino acids in Wilson's disease [56]. In the succeeding 10 years it has become clear that the renal lesion in Wilson's disease is extremely diffuse and affects many aspects of renal function [57].

### *Renal Hemodynamics*

In most cases of Wilson's disease there is a marked and consistent reduction of renal plasma flow and a distinctly decreased glomerular filtration rate. In general the degree of impairment parallels the severity and duration of overt disease. In some instances albuminuria can be demonstrated. There may be impairment in urine concentrating ability.

### *Tubular Reabsorptive Mechanisms*

The tubular secretory capacity is usually diminished as judged by impairment of the  $Tm_{\text{PAH}}$ . Associated with this defective function a diminished effect of probenecid in eliciting a further reduction of  $Tm_{\text{PAH}}$  can be demonstrated.

### *Amino Acids*

Impairment of renal tubular reabsorptive activities in Wilson's disease has been thoroughly demonstrated. The excessive aminoaciduria can be attributed to a defective renal reabsorption since qualitatively and quantitatively the amino acids in the serum are not elevated. It is known

that the various amino acids are not reabsorbed in the tubules by a common process thus it is of interest to examine the distribution of the amino acids excreted in the urine in patients with Wilson's disease. It should be emphasized that increased aminoaciduria is not a constant feature of the disease and is usually present only in those patients in whom the disease is of long standing. In general it appears that the largest excretion relative to normal subjects occurs with threonine and cystine excretion of which may be elevated twentyfold [58]. Indeed the excretion of cystine in Wilson's disease may exceed that found in patients

TABLE 25-3 URINARY AMINO ACID EXCRETION IN WILSON'S DISEASE

| Diminished         | Normal             | Increased<br>(X normal) |            |           | Excretion<br>of amino<br>acids not<br>found in<br>normal<br>urine |

|                    | Arginine           |                         | Valine     |           |   |
|                    |                    |                         | Tyrosine   |           |   |
|                    |                    |                         | Lysine     |           |   |

SOURCE: W. H. Stein et al. [58].

with cystinuria. It is of interest that patients with Wilson's disease usually do not form cystine stones. The excretion of other amino acids in relation to the normal excretion is illustrated in Table 25-3.

The urinary excretion of amino acids in Wilson's disease can vary markedly depending upon the state of the disease and the composition of the diet.

In addition to an increased excretion of free amino acids there is an increased excretion of amino acids in the form of conjugated linkages from which the free acids are liberated by hydrolysis with acid. These bound amino acids excreted in quantities about double those of the normal urine thus represent a smaller proportional elevation than that found for free amino acids [53].

In recent years Uzman has emphasized that one of the cardinal abnormalities in Wilson's disease is the excretion of specific oligopeptides [59]. These are thought to be formed by an abnormal proteolytic enzyme in the tissues and to cause an intracellular accumulation of oligopeptides

plasmin is evidence of a failure to exchange the radioactive copper with the nonradioactive copper, or whether, as seems more likely, it is due to an alteration in the structure of ceruloplasmin, remains to be determined.

Since the total body copper is increased in Wilson's disease and because the urinary excretion is elevated, it is clear that an increased quantity of dietary copper must be absorbed through the intestinal tract. Balance studies have tended to indicate that increased absorption does indeed occur, as does a decreased excretion of copper through the intestinal tract. The use of radioactive copper has enabled the increased absorption of copper to be demonstrated clearly [52].

Uptake of  $\text{Cu}^{64}$  by erythrocytes (in erythrocytuprein) of patients with Wilson's disease is similar to that of normal subjects. This emphasizes the rather specific nature of the ceruloplasmin defect in this condition [52]. An explanation for the hemolytic anemia found in some patients with Wilson's disease is not readily deduced from the studies on copper metabolism of the red cell [54].

## RENAL ABNORMALITIES IN WILSON'S DISEASE

In 1948 Uzman and Denny Brown reported an increased amino aciduria in patients with Wilson's disease [55]. Dent in the previous year had also observed an increased excretion of amino acids in Wilson's disease [56]. In the succeeding 10 years it has become clear that the renal lesion in Wilson's disease is extremely diffuse and affects many aspects of renal function [57].

### *Renal Hemodynamics*

In most cases of Wilson's disease there is a marked and consistent reduction of renal plasma flow and a distinctly decreased glomerular filtration rate. In general the degree of impairment parallels the severity and duration of overt disease. In some instances albuminuria can be demonstrated. There may be impairment in urine concentrating ability.

### *Tubular Reabsorptive Mechanisms*

The tubular secretory capacity is usually diminished as judged by impairment of the  $Tm_{\text{PAH}}$ . Associated with this defective function is a diminished effect of probenecid in eliciting a further reduction of  $Tm_{\text{PAH}}$  which can be demonstrated.

### *Amino Acids*

Impairment of renal tubular reabsorptive activities in Wilson's disease has been thoroughly demonstrated. The excessive aminoaciduria can be attributed to a defective renal reabsorption, since qualitatively and quantitatively the amino acids in the serum are not elevated. It is known

that the various amino acids are not reabsorbed in the tubules by a common process thus it is of interest to examine the distribution of the amino acids excreted in the urine in patients with Wilson's disease. It should be emphasized that increased aminoaciduria is not a constant feature of the disease and is usually present only in those patients in whom the disease is of long standing. In general it appears that the largest excretion relative to normal subjects occurs with threonine and cystine excretion of which may be elevated twentyfold [58]. Indeed the excretion of cystine in Wilson's disease may exceed that found in patients

TABLE 25-3 URINARY AMINO ACID EXCRETION IN WILSON'S DISEASE

SOURCE: W. H. Stein et al. [58].

with cystinuria. It is of interest that patients with Wilson's disease usually do not form cystine stones. The excretion of other amino acids in relation to the normal excretion is illustrated in Table 25-3.

The urinary excretion of amino acids in Wilson's disease can vary markedly depending upon the state of the disease and the composition of the diet.

In addition to an increased excretion of free amino acids there is an increased excretion of amino acids in the form of conjugated linkages from which the free acids are liberated by hydrolysis with acid. These bound amino acids excreted in quantities about double those of the normal urine thus represent a smaller proportional elevation than that found for free amino acids [58].

In recent years Uzman has emphasized that one of the cardinal abnormalities in Wilson's disease is the excretion of specific oligopeptides [59]. These are thought to be formed by an abnormal proteolytic enzyme in the tissues and to cause an intracellular accumulation of oligopeptides

within the tissues. Some of the excreted peptides compete with the amino acids for reabsorption by the proximal renal tubules and, because the copper peptide complex is absorbed preferentially, an aminoaciduria results. In discussions of this hypothesis it should be recalled that the liberation of amino acids on acid hydrolysis of urine is not evidence per se of the existence of peptides. At least 75 per cent of the amino acids liberated by acid hydrolysis of human urine derives from compounds other than peptides [60]. A considerable proportion of the increase in the amounts of glutamic and aspartic acids after acid hydrolysis arises from the decomposition of glutamine and asparagine. Other compounds include such substances as hippuric acid, phenacetylglutamine and tyrosine O sulfate. However, small quantities of peptides undoubtedly exist in normal urine and may be presumed to exist in the urine of patients with Wilson's disease. Unequivocal demonstration of their presence will be awaited with interest.

### *Glucose*

Glycosuria may be present in some patients with Wilson's disease. It is significant that although in many patients spontaneous glycosuria may be absent or minimal, the maximum tubular capacity to reabsorb glucose is frequently substantially reduced [57]. These observations emphasize that a failure to find an increased excretion of glucose does not preclude a considerable defect in the capacity of the renal tubules to transport glucose across the tubular epithelium.

### *Bicarbonate*

A tendency to excrete an alkaline urine in patients with Wilson's disease has been described and is associated with the renal excretion of bicarbonates at plasma levels that would ordinarily demand complete reabsorption of bicarbonate by the renal tubules.

### *Uric Acid*

In 1954 Bishop and coworkers reported a low serum uric acid associated with an increased urinary uric acid excretion in a brother and sister with Wilson's disease [61]. Subsequent investigators have confirmed these findings, and renal clearance studies have demonstrated that, as originally postulated, the diminished reabsorption of filtered urate accounts for both the increased urinary excretion and the low serum urate levels observed. The capacity of probenecid further to increase the  $C_{\text{rate}}$  to  $C_{\text{cr}}$  diminished as the tubular transport systems for urate deteriorated with progression of the disease [57]. The low serum uric acid level is so constant a feature of Wilson's disease that a serum uric acid determination should be performed in all cases of cirrhosis of unexplained origin and in all obscure diseases of the central nerv-

ous system in which disturbances of the function of the basal ganglia are prominent

### Phosphate

A low serum inorganic phosphate level occurs in a high proportion of patients with Wilson's disease [67]. Renal clearance studies have revealed an even higher proportion of patients in whom the  $C_{Cr}$  is increased. Thus

Fig 25-6 Radiograph illustrating fracture head of the right radius showing no evidence of bone union (Reproduced from A G Bearn [66])

a failure of normal tubular transport of phosphate is a common feature of the disease and may be in part responsible for the occasional appearance of clinical osteomalacia and spontaneous fractures (Fig 25-6) [62-63]

### Calcium

Hypocalcaemia occurs in many patients with Wilson's disease and is also related in part to the duration of the overt disease [63a]

## THE ABNORMALITY IN WILSON'S DISEASE

In the preceding pages the various abnormalities in copper metabolism and renal function have been discussed and the two current hypotheses of the pathogenesis of the disease briefly mentioned. These two hypotheses will now be discussed in detail.

### Abnormality of Copper Metabolism

In its simplest form this hypothesis suggests that the primary effect of the abnormal gene is to diminish the synthesis of normal ceruloplasmin

and conceivably of other closely related proteins. In a way which is not understood this leads to an increased absorption of copper from the intestinal tract, and this in turn to an excessive deposition of copper in the tissues with consequent functional and structural alterations. Although the copper content of many organs is increased certain tissues such as the basal ganglia of the brain, liver cells and Descemet's membrane of the cornea appear to be selected preferentially. The differential deposition of copper in various tissues could be ascribed to the variation of copper binding capacity of normal proteins and related substances in different tissues. No postulation that these tissue proteins are abnormal would be necessary. Thus the disturbed liver function leading eventually to cirrhosis of the liver, the cerebral damage, and the disturbance in renal function are all ultimately consequent upon the effect of copper on a variety of enzyme systems throughout the body. The decreased ceruloplasmin level observed in some individuals who are heterozygous indicates that even in single dose the abnormal gene may have an observable metabolic defect but without causing manifest clinical disease.

When this hypothesis is stated in this simple way many experimental observations do not fit. (1) There is no correlation between the depression of ceruloplasmin synthesis and the amount of copper absorbed. (2) Experimental administration of copper to a variety of animals has failed to mimic the disease. (3) Some patients with Wilson's disease have a serum ceruloplasmin level which is quantitatively normal. (The direct reacting copper level is usually elevated in these individuals, this probably reflects the increased body stores of copper.) (4) There is relatively little correlation between the increased amount of copper excreted in the urine and the clinical improvement which may follow the use of British anti-lewisite (BAL) and penicillamine. Many of these objections do not by themselves invalidate this hypothesis but serve to emphasize its considerable defects.

A reasonable hypothesis for the renal lesion ascribes the progressive deterioration in renal function to the march of copper to sites where it can interfere with enzyme systems responsible for the transport of materials across epithelial membranes. Such a hypothesis gains some support from observations on poisoning with other divalent metals in which most of the damage falls, as it does in Wilson's disease, on the proximal renal tubules. It seems plausible that the renal abnormalities can be ascribed to a disturbance in copper metabolism, and are not a direct consequence of the abnormal gene on renal function.

#### *Abnormality of Peptide Metabolism*

An alternative hypothesis has been postulated by Uzman and outlined by him in a series of papers [69 64 65]. This hypothesis ascribes the primary effects of the abnormal gene to an abnormal protein which has

an increased capacity for binding ionic copper. This protein is present in the liver (and presumably in every tissue in which the copper content is increased). The increased affinity of copper for certain tissues blocks the formation of ceruloplasmin, thus the diminished ceruloplasmin level is a secondary phenomenon and is due to the diversion of copper to the tissues. In addition the abnormal protein metabolism in the tissues is said to give rise to specific oligopeptides which compete with amino acids and uric acid for reabsorption in the proximal renal tubules, causing aminoaciduria and uricosuria. Cirrhosis of the liver is ascribed to a nutritional deficiency.

This hypothesis, currently less favored than the first, also contains some unsatisfactory features. Quantitative considerations make it extremely improbable that the renal loss of amino acids could give rise to hepatic cirrhosis, and indeed many cases of Wilson's disease have been reported in which no aminoaciduria is present but in whom a diminished ceruloplasmin is evident [58-66]. The difficulties and uncertainties in the peptide hypothesis for the urinary abnormalities have been outlined in an earlier section and have been dealt with at length by Walshe [67]. According to this hypothesis it would be anticipated that intravenously administered radioactive copper would disappear from the circulation more rapidly rather than more slowly if the tissue proteins had an increased affinity for copper. Thus it can be seen that neither hypothesis can be regarded as more than tentative; the problem will be resolved not by debate but by the collection of more data.

## GENETICS

In his original monograph Kimmel Wilson pointed out that familial incidence is one of the striking features of the disease. Although he considered the possibility that the disease was inherited, the familial incidence was attributed to environmental rather than genetic causes [1]. This view, with some notable dissent [68], was held until relatively recently.

Study of a large number of patients with Wilson's disease has permitted a genetic analysis [69-70]. Inspection of the pedigrees immediately confirmed the familial concentration observed by Wilson and in addition disclosed that many of those afflicted were the offspring of consanguineous unions (Table 25-4).

This remarkably high consanguinity rate is good evidence that the disease is inherited in an autosomal recessive fashion (Table 25-4). Calculations based on the incidence of Wilson's disease in siblings when the parents are unaffected are in accord with this hypothesis [70]. The method of calculation used is variously known as Hoggan's factorial method or the a priori method of Bernstein.

TABLE 25-4 THE CONSANGUINITY RATE IN 30 FAMILIES WITH WILSON'S DISEASE

| No of sibships | Consanguinity rate in parents of patients with Wilson's disease |            |                |            |           |            |

SOURCE Adapted from A. G. Bearn [70a]

*Sex Incidence*

The disease is probably slightly more common in males than females. Most series of cases show a slight excess in males which because of the small numbers is statistically insignificant. In our series 21 of 32 patients were male.

*Age of Onset*

The age of onset of Wilson's disease is variable and does not differ in the two sexes (Table 25.5). The apparent excess of Jewish males when the

SOURCE Adapted from A. G. Bearn [70a]

disease has a late onset raises the problem of genetic heterogeneity. The possibility exists that the allele causing disease in this group of patients is different from the usual allele. A modifying gene which delays the onset of the disease could also be responsible for the late onset in these patients.

### *Racial Incidence*

Of the 30 families in New York City in whom individuals with Wilson's disease were discovered 13 (43 per cent) were Jewish who came from the border of Russia and Poland within a radius of approximately 100 miles. If a mutation occurred in this population the breeding structure would favor the formation of many homozygotes. Seven of the 30 families (23 per cent) were Italians who came from Sicily and the southernmost tip of Italy. The breeding structure in this isolated area would also tend to produce individuals homozygous for the abnormal gene. Nearly all the remainder of the patients of this series came from various parts of Europe. Two of the 30 families (7%) were Negroes. The disease has also been recorded in Chinese, Malaysians, Japanese and Eskimos [70b]. Whether the original mutations which occurred in Eastern Poland and Sicily were identical is not clear. In interpreting these data it must be recalled that these patients were largely collected from New York City and that their racial distribution reflects to some extent the geographic origins of the population of New York.

### *Gene Frequency*

Estimations of gene frequency are fraught with considerable hazard. One of the essential assumptions, namely, that the disease is genetically homogeneous, may be unjustified. Another difficulty encountered if the method devised by Dahlberg [71] is used is the uncertainty of the estimate of the frequency of first cousin marriage in the population from which the sample is drawn. Few precise data are available concerning the estimate of the first cousin consanguinity rate in the populations of Eastern Poland or Sicily 50 years ago. To be sure the figure of 1/1000 estimated by Julia Bell [72] for England is far too low and would give too low an estimate of the gene frequency. If accurate data on the consanguinity rate were known it would be possible to give a rough estimate of the gene frequency in the original populations in Eastern Poland and Sicily. It is impossible, however, to determine the gene frequency in America with any accuracy. As a very rough estimate, if the consanguinity rate in America is assumed to be 1/1000, the calculated gene frequency would be approximately 1/2000, with a disease incidence of 1/400000. It should be emphasized that such calculations are almost valueless in a rare recessive disease in which the condition may have arisen by mutation in a very small community in which consanguineous unions were very numerous.

### *Detection of Carriers*

The detection of asymptomatic carriers of deleterious genetic traits is being attempted in many heritable disorders. Related to this problem

but frequently more difficult to demonstrate is the important question of whether the heterozygote possesses any increased biologic fitness over either homozygote [73]. Unfortunately, with a disease as rare as Wilson's disease it would be virtually impossible to demonstrate any heterozygous advantage.

If the gene product were known with certainty, then its estimation should enable a differentiation between the three genetic groups—homozygous normal, homozygous affected and heterozygous—although some degree of overlap might be expected. Ceruloplasmin depression is a relatively constant biochemical abnormality in patients with Wilson's disease; has been found in some heterozygotes, and not in others [70, 74, 75]. In addition some asymptomatic siblings without Kayser-Fleischer rings have had a low level of ceruloplasmin and were found unable to incorporate  $\text{Cu}^{++}$  into ceruloplasmin [46]. A preliminary study of 10 heterozygotes with normal ceruloplasmin levels has demonstrated less incorporation of ingested  $\text{Cu}^{++}$  into ceruloplasmin than normal [76]. The possibility that aminoaciduria could be detected in asymptomatic siblings of patients with Wilson's disease has been investigated. The first reports indicated that aminoaciduria could be detected in relatives of those affected [51]. Subsequent work has failed to confirm the early findings [47].

There is evidence that the disease in certain families conforms to a distinctive clinical and biochemical pattern. In any one sibship the age of onset, the predominant clinical symptoms, and the biochemical abnormalities may be remarkably similar. In some families only the hepatic form of the disease is present, in others the liver injury is minimal and neurologic symptoms are prominent. The possibility cannot be dismissed that these two clinical syndromes are due to different alleles which may not even be at the same locus [70].

Muller has recognized two categories of gene products which he has called amorphs and neomorphs. The first is associated with an absence of the gene product and the latter with the formation of a new and altered gene product. Wilson's disease may prove to be an example of a disease which is amorphic (usually hypomorphic) but which may occasionally prove to be neomorphic.

## TREATMENT

Until some of the biochemical features outlined in the preceding pages became delineated the treatment of Wilson's disease was entirely symptomatic. On the assumption that some if not all of the symptoms in Wilson's disease may be related to the increased total body copper measures designed to decrease the tissue copper stores might be expected to be therapeutically beneficial.

It is not possible to reduce the copper content of the diet below 1.0 mg per day without considerable caloric restriction. The ingestion of carbo

resins and potassium sulfide has been advocated to reduce copper absorption

In addition to diminishing the copper intake efforts should be made to achieve a large and persistent increase in urinary copper excretion. A variety of agents which chelate copper have been used with success. BAL introduced by Denny Brown [77] has proved a valuable agent in increasing the urinary excretion of copper. It suffers from the disadvantage that it must be suspended in peanut oil and administered by intramuscular injection. Local induration or abscesses may occur at the site of injection. Moreover, toxic reactions to BAL are not uncommon. These include high fever, faintness, nausea and vomiting. Intravenous disodium versenate is an effective cupruric agent, but the necessity for intravenous injection of this compound precludes its continued use.

The introduction of penicillamine ( $\beta\beta$  dimethylcysteine) in 1956 by Walshe was a landmark in the development of therapeutic measures for increasing the urinary excretion of copper [78]. This compound, which can be given by mouth, is in the practical dosage range a much more effective cupruric agent than BAL, and its administration is not accompanied by so many side reactions. Toxic reactions may occur, however, and resemble those seen in penicillin sensitivity. Fever, various drug rashes, and leukopenia have been observed. Pharmacologic studies of the two enantiomorphs—D penicillamine and L-penicillamine—indicate not only that the D form is the more effective in protecting rats against mercury poisoning, but that the L-form has serious toxicity for the animals [79]. Such studies do not argue strongly in favor of clinical use of the D-optical isomer rather than the DL-mixture, but indicate the need for a comparative therapeutic evaluation.

One of the difficulties encountered in the treatment of Wilson's disease has been the tendency of patients to become resistant to the cupruric agent, and a prolonged cupruric effect may be difficult to achieve. Presumably, the copper easily removed is that recently deposited, whereas the fraction of copper corresponding to cerebrocuprein II is less easily chelated. None of the chelating agents consistently lowers the serum ceruloplasmin level. The excretion of amino acids or other substances absorbed by the proximal renal tubules and excreted in excess in Wilson's disease is not affected by the administration of BAL or penicillamine.

Varying combinations of these therapeutic measures have been found beneficial in management of patients with this disease. The optimum program of administration of the chelating agents has not been clearly defined. The natural course of the disease, though more often inexorably downhill if untreated, may be prolonged and subject even to periods of improvement. This makes evaluation of therapy difficult. Dramatic improvement, sometimes sustained for long periods, may follow the use of penicillamine or BAL.

## SUMMARY

1 Wilson's disease (hepatolenticular degeneration) is a rare inherited disease which usually occurs in young people. Pathologically it is characterized by cirrhosis of the liver and degenerative changes in the brain particularly in the basal ganglia. Kayser Fleischer corneal rings are pathognomonic of the disease. An increased absorption of dietary copper from the intestinal tract with consequent increased deposition of copper in the tissues can be demonstrated. The increased copper in the body is localized primarily in the liver, brain, kidneys and cornea. The administration of radioactive copper can increase the number of heterozygotes in whom abnormalities in ceruloplasmin can be detected.

2 Biochemical abnormalities in Wilson's disease are multiple. Low serum copper and decreased serum ceruloplasmin levels are observed in the majority of patients with the disease and are associated with an increased urinary excretion of copper. The plasma levels of amino acids and glucose are usually normal or slightly decreased. The serum phosphate level is often decreased and the serum uric acid usually decreased.

3 Abnormalities in renal function are demonstrable; they consist of a progressive failure of tubular transfer mechanisms for amino acids, glucose, uric acid and phosphate.

4 Family studies indicate an autosomal recessive inheritance pattern. Decreased serum copper and serum ceruloplasmin are occasionally found in clinically normal heterozygotes.

5 The pathogenesis of the disease is obscure. Whether it is a general abnormality of protein metabolism in which specific tissue proteins bind copper preferentially or whether as seems more likely the primary disturbance is one of copper metabolism remains to be determined. The abnormality usually results in a decreased synthesis of normal ceruloplasmin. However the possibility that synthesis of an abnormal ceruloplasmin may perhaps occur must be considered.

## Chapter 26

### Hemochromatosis

---

Ralph L. Peterson

Hemochromatosis is a form of iron storage disease characterized by the deposition of abnormally large quantities of iron in various organs or tissues of the body. It was probably first reported as a morbid entity by Troisier in 1871 [1] under the designation *la cirrhose pigmentaire dans le diabete sucré* although Trousseau [2] probably described a case in 1865 in the course of a clinical lecture on glycosuria. The term *hemochromatosis* was first introduced by von Recklinghausen in 1889 [3] to describe the clinical triad of generalized pigmentation, enlarged and cirrhotic liver, and diabetes mellitus. He used the term because he considered the disease an example of a hemorrhagic diathesis. The excess pigment in the tissue was presumed to arise from the breakdown of hemoglobin. The disease has also been referred to as bronzed diabetes, pigment cirrhosis, siderochromatosis, and primary congenital idiopathic or endogenous hemochromatosis.

The term *primary hemochromatosis* will be reserved here for the idiopathic form of iron storage disease which in untreated patients eventually progresses to the classical pathologic triad of cirrhosis of the liver, brown discoloration of the skin, and diabetes mellitus. Primary hemochromatosis probably represents an inherited metabolic disorder as first suggested by Sheldon in 1927 [4]. The disease is now known to be associated with an increased gastrointestinal absorption of iron.

#### DEFINITIONS

It is necessary to differentiate among the various conditions associated with increased body iron stores (Table 26-1).

Hemochromatosis, the form of tissue iron deposition associated with characteristic morbid changes, may be primary or secondary.

*Primary or idiopathic hemochromatosis* is a specific disease entity

It is one of several forms of iron storage disease known collectively as hemosiderosis (a descriptive histologic term). The increased iron stores in primary hemochromatosis result from increased absorption of the mineral from a normal diet. The increased iron absorption is not secondary to any known cause such as increased oral iron intake or erythroid hyperplasia. It is believed that this disease represents a genetically determined error of metabolism. Primary hemochromatosis usually begins in adult life and is much more common in males than in females.

TABLE 461 IRON STORAGE DISEASE

| Type                      | Cause of increased iron stores                             | Percentage of diet iron absorbed |
|---------------------------|--|----------------------------------|
| Hemochromatosis           |  |                                  |
| Primary                   | Inborn error of metabolism                                 | Increased                        |
| Secondary                 | Increased erythroid activity<br>Excessive oral iron intake | Increased<br>Normal              |
| Siderosis                 |  |                                  |
| Localized                 | Pulmonary hemosiderosis                                    | Normal                           |
| Generalized               |  |                                  |
| Transfusion hemosiderosis | Transfused blood   | Normal                           |
| Cytosiderosis (Bantu)     | Dietary deficiency plus excessive dietary iron             | Normal                           |
| Kashin-Bek disease        | Increased iron content of drinking water                   | Normal                           |

Secondary hemochromatosis is a form of siderosis which may result from increased iron absorption secondary to known causes. The most common of these is erythroid hyperplasia associated with hemolytic [5] pernicious [6] primary hyperplastic refractory [7-9] or Cooley's anemia [10-12], and chronic erythremic myelosis [13]. The anemias are frequently megaloblastic [6-8, 14]. Hemochromatosis has also been documented in hereditary hypochromic anemias [15, 16]. Secondary hemochromatosis must be extremely rare in patients with aplastic anemia who do not have an erythroplastic marrow [17]. Patients who develop hemochromatosis in association with anemia have frequently received large amounts of transfused blood. It was once thought that the transfused red cells represented the sole source of the increased iron stores found at autopsy. Houston, however, reported a case in a man with long-standing macrocytic refractory anemia who had been given no transfusions [18]. Secondary hemochromatosis has been reported in patients with mild anemia who have received no transfusions but who have received large doses of medicinal iron for many years [1, 19]. One female patient was presumed to have taken over 25,000 gm iron over a 47-year period [20].

Secondary hemochromatosis is frequently indistinguishable pathologically from the idiopathic type [9 12 15 18]. The pathologic changes usually develop while the patient has a normal dietary iron intake. Increased iron absorption has also been demonstrated in this group of patients [31]. The secondary type differs from the primary in that it may begin in childhood [22] and there is equal sex incidence.

*Siderosis* is a condition characterized by increased tissue iron without many of the clinical and pathologic features of either primary or secondary hemochromatosis. The term was first used by Quincke [23] for accumulated iron deposits in the tissues and organs under various conditions. Localized accumulations of iron may occur as a result of hemorrhage into the tissues producing a siderosis localized to a particular tissue as in pulmonary hemosiderosis. Neumann [24] first proposed the term *hemosiderin* for the microscopically visible tissue iron containing brown pigment.

*Transfusion hemosiderosis* is due entirely to the overloading of the tissues from iron contained in transfused red cells and is thus a true hemosiderosis since the excess stores arise from hemoglobin iron. The first record of an example of this condition was made by Hark who described two cases of aplastic anemia [25]. Since that time the condition though rare has been reported in about seventy cases [26-33]. The quantities of iron deposited in the tissues usually do not equal those found in hemochromatosis except when 200 or more blood transfusions have been given. The iron is deposited predominantly in the reticuloendothelial rather than the parenchymal cells and is therefore especially heavy in the bone marrow kidney and spleen [33 34]. The serum iron may be normal. Finely granular cirrhosis of the liver cardiac dysfunction and fibrosis of the pancreas are not found diabetes mellitus gonadal hypoplasia and skin pigmentation occur infrequently and are usually mild. Increased iron absorption probably does not occur in patients not having erythroid hyperplasia but patients with this latter condition may have increased tissue iron stores secondary to transfused red cell iron and increased iron absorption.

*Cytosiderosis* is endemic in the Bantu in certain areas in South Africa and is probably not a specific disease entity. It is a pathologic process that appears to begin in childhood [35 36] and occurs in individuals with malnutrition or pellagra whose diet contains very large amounts of iron [37]. It may progress to fibrosis and siderosis of the liver but diabetes and fibrosis of the pancreas do not occur and cardiac function is not impaired [38]. Increased tissue iron may also occur in severe malnutrition [39].

*Kaschin Beck disease* is a form of iron storage disease that appears to be restricted largely to Manchurian hunters and farmers [40] and is endemic in areas where drinking water with a very high iron content (0.3 to 1.0 mg per liter) is consumed during childhood and puberty. The

major changes appear in the skeletal system as shortened long bones and short stature joint deformities and arthritis particularly of the interphalangeal joints. A minimal fibrosis of the liver may occur without cirrhosis pancreatic fibrosis, or cardiac dysfunction. Skin pigmentation and elevated serum iron values may be present.

## CLINICAL FEATURES

Hemochromatosis occurs sporadically throughout the world and although it is rare cases have been reported from most countries. There appears to be no particular geographic distribution but the incidence may be lower in areas where iron deficiency is prevalent and higher in areas where increased dietary iron intake or certain refractory anemias are more common [41-43]. Environmental and dietary factors other than iron intake may play a role in influencing the age of onset of the disease. The frequency of the disease has not been correlated with occupation or exposure to toxic agents.

Extensive descriptions of the clinical features of hemochromatosis have been presented by Sheldon [41], Hellmeyer [43] and several American authors [42, 44-46].

### *Symptoms and Signs*

The asymptomatic interval preceding the development of the clinical features covers many years and the disease is seldom recognized during this stage unless by chance as the result of a tissue biopsy or plasma iron determination. Although symptoms and signs may have their onset earlier the full complex has not been reported prior to the age of 20 years [41]. Hemochromatosis developing in early adulthood is frequently fulminating and carries an unfavorable prognosis. In most cases the symptoms start in the middle years (in 90 per cent after the age of 30). The disease starts earlier in males and is ten to twenty times more common in males than in females. The comparative rarity of hemochromatosis in females and the later age of onset may be due to the increased iron deficits that result from menstruation, pregnancy and lactation. Throughout the sexually productive years the average woman may lose from 10 to 15 gm iron through menstruation. A single pregnancy and lactation may contribute to the loss of another 0.5 gm iron.

The symptoms most frequently encountered initially are those related to the classical triad of diabetes, skin pigmentation and cirrhosis. Although the liver is the first tissue to contain large deposits of iron the early symptoms of weakness, malaise and weight loss may most likely be related to the diabetes mellitus. Skin pigmentation develops insidiously and is followed by symptoms related to cirrhosis of the liver e.g. abdominal pain and ascites. Dyspnea and edema resulting from impaired cardiac

function and loss of libido as a consequence of involvement of the endocrine organs (testes) may next make their appearance

Skin pigmentation and hepatomegaly are the most constant physical signs of hemochromatosis and develop earliest. The brownish pigmentation is primarily the result of increased melanin deposition in the skin and appears early, with the increased deposition of iron in the integument a brownish gray (metallic bronze or slate) color makes its appearance. Pigmentation of the skin is usually generalized but it appears first and is most intense over the exposed areas and extensor surfaces of the arms, external genitalia, nipples and scars. Except for the less frequent mucous membrane pigmentation the distribution and appearance of the brownish pigmentation resembles that seen in Addison's disease [47].

The liver usually becomes enlarged long before signs and symptoms of hepatic dysfunction develop. Fibrosis and dysfunction of the liver underlie such characteristic signs of cirrhosis as spider angiomas and palmar erythema. Body depilation, loss of libido, testicular atrophy and gynecomastia may also be partially related to liver failure. With the steady progression of fibrosis and liver failure, the signs and symptoms and liver function test results become indistinguishable from those of typical Laennec's portal cirrhosis. With the onset of portal hypertension splenomegaly may appear. Such complications as ascites, edema and bleeding from esophageal varices appear to be much less common in hemochromatosis with cirrhosis than in typical Laennec's cirrhosis. Many patients with hemochromatosis of long duration develop primary carcinoma of the liver [42]. Cardiac failure and primary carcinoma of the liver may frequently contribute to the ascites and edema.

X-ray examination of the abdomen may demonstrate an increased density of the liver because of the high iron content. This is sometimes not prominent as a sharp line just below the shadow of the right diaphragm [42].

The myocardium is gradually involved; this is manifested by the signs and symptoms of congestive failure and cardiac arrhythmias [48, 49]. When cardiac failure develops there usually is dilatation of both ventricles with a globular cardiac profile resembling that occurring with pericardial effusion. In the younger subjects cardiac disturbances may progress rapidly and lead to sudden death. Cardiac failure now constitutes the single leading cause of death in hemochromatosis prior to the use of insulin; the leading cause was diabetes. Hypertension is rarely seen in hemochromatosis.

Endocrine dysfunction is manifested by loss of body hair, testicular atrophy, gynecomastia and menstrual irregularities. Loss of libido progressing to complete impotency may develop. The effects may in part be the result of impaired liver function.

Pain in the extremities, cutaneous hyperesthesia and muscle and leg

cramps frequently appear as a late complication of hemochromatosis these symptoms do not seem to be attributable to the diabetes mellitus. Psychic disturbances may also appear, and iron may be deposited in various areas of the brain [50].

Iron deposits occur focally in the renal tubules but do not affect renal function. There is no significant hematologic disturbance in primary hemochromatosis and the bone marrow is usually normal. The absence of hematologic involvement usually differentiates the idiopathic or primary disease from secondary hemochromatosis.

### PATHOLOGY

The pathology of hemochromatosis has been frequently reviewed [28-32, 41, 42, 51].

The liver is usually greatly enlarged and has a rusty appearance with a 'hobnail' surface. Microscopically, there is an advanced finely granular cirrhosis of the multilobular or portal type. Areas of regeneration are prominent. There is degeneration of the liver cells and a large amount of the iron may be present extracellularly or within the Kupffer cells. The large size of the liver, the small regenerative nodules of liver cells and the absence of broad bands of atrophy characteristically differentiate this disease from postnecrotic cirrhosis. Hemosiderin and hemofuscin pigments are present and the former is strikingly increased within the liver parenchymal cells. In the various other forms of siderosis the iron content of the liver is usually not so great and the largest quantity of iron is within the Kupffer rather than the parenchymal cells [30, 33, 36]. In typical Laennec's cirrhosis with siderosis the iron is also predominantly within the Kupffer cells and the liver is usually small [31]. Although fibrosis of the liver may occur in other forms of siderosis, finely granular cirrhosis does not [30, 32, 36].

The pancreas shows a heavy brown discoloration and except for the liver contains the largest amount of iron. There is a great increase in fibrous tissue. The gland cells show degenerative changes and siderosis and in most cases the islet cells are affected. It has been proposed on the basis of studies of 62 patients with diabetes secondary to hemochromatosis that the diabetes does not predispose to renovascular disease and that the diabetes of hemochromatosis probably represents a true insulin deficiency [52]. Diabetes mellitus occurs less frequently in siderosis uncomplicated by secondary hemochromatosis [9, 33]. The salivary glands like the pancreas usually show a deep brown red discoloration and the glandular epithelium contains large deposits of hemosiderin.

The spleen is usually only slightly enlarged. Hemosiderin deposits appear in very much smaller amounts than in the liver and pancreas. This

■ in contrast to the greater splenomegaly and much higher iron content of the bone marrow kidney and spleen in transfusion hemosiderosis [33 34]

The mucous membrane of the entire gastrointestinal tract may be pigmented The hemosiderin deposits are heaviest in the glandular epithelium of the stomach duodenum and cecum although there appears to be no alteration in the structure of the organs

The heart is usually a deep brown color Microscopically the endocardium and pericardium are not involved and the pathologic changes are confined entirely to the myocardium which may contain large amounts of hemosiderin Degenerative changes are seen in the muscle fibers and the increased fibrous tissue may replace the muscle

The pituitary usually shows a brown discoloration from increased deposits of hemosiderin localized to the cells of the anterior lobe The testes are usually atrophic and on microscopic examination show atrophy of the germinal epithelium The deposits of hemosiderin are usually not large and fibrous tissue is not increased The ovaries usually do not contain increased quantities of hemosiderin The parathyroid glands are frequently heavily pigmented without overgrowth of fibrous tissue The thyroid also shows a brownish pigmentation and microscopically there are marked overgrowth of fibrous tissue and increased quantities of hemosiderin within the alveolar epithelium

The adrenal glands do not appear altered grossly and there is no increase in connective tissue The microscopic changes are localized to the cortex and in most cases are confined to the outer zona glomerulosa Hemosiderin when present is always found in the glomerulosa and frequently only in this zone Hellier [47] reported a correlation between the degree of melanin pigmentation and the amount of iron deposited in the zona glomerulosa At autopsy one case of classical hemochromatosis with minimal pigmentation was found to have no iron deposits in the zona glomerulosa [38] In the various forms of siderosis the endocrine organs are not usually heavily laden with iron except for the deposits within the zona glomerulosa Some investigators [47 53-55] have alluded to a possible relationship between the skin pigmentation infrequent hypertension and more frequent hypotension and adrenal insufficiency secondary to the iron deposits in the adrenal cortex Studies of adrenal function in hemochromatosis have not been made although low values for both urine corticosteroid and 17 ketosteroid might be expected because of the cirrhosis [56] Simpson [37] reviewed the reported cases of Addison's disease with diabetes mellitus and could find only two with hemochromatosis Since the zona glomerulosa is most heavily laden with iron deposits it might be expected that aldosterone metabolism would be altered earliest

the apoferritin content of the mucosal cells of the stomach and duodenum [79] Ferritin is not normally present in the plasma but it may appear there in patients with toxic hepatitis [80]

Hemosiderin is the iron hydroxide-protein complex that is visible microscopically in the tissues as brownish granules. It remains insoluble under the conditions (neutral aqueous solution) used for the extraction of ferritin from the tissues [81] Hemosiderin contains relatively less protein than ferritin and consequently more iron. The iron content may range from 30 to 35 per cent and the iron to nitrogen ratio is 5-9:1. Hemosiderin and ferritin both give the Prussian blue reaction but in tissues the visible Prussian blue color is usually produced only by hemosiderin that is clumped in large granules. Studies with the electron microscope show that some of the hemosiderin deposits are contained within membranes ('siderosomes') and that some of the brown clusters of pigment may be predominantly ferritin [82]. Thus a significant portion of apparent hemosiderin may represent iron rich molecules of ferritin. Both hemosiderin and ferritin iron are utilized for hematopoiesis [83-84] although the latter is probably utilized more efficiently.

Transport iron in the plasma (3 to 4 mg) represents the link between the various tissue iron compartments. In the presence of oxygen ferrous iron entering the plasma is quickly oxidized to the ferric form which is then transported by a specific iron binding  $\beta$  globulin siderophyllin or transferrin [85]. The trivalent iron is bound to this protein with ionic bonds [86]. Normally the iron binding protein accounts for only about 3 per cent of the total plasma protein and is only about one third saturated with iron. Transferrin in man is not a single protein species. The different transferrins have been identified as the proteins involved in the genetically controlled variations of the serum  $\beta$  globulins in human beings [87]. A deficiency of transferrin has not been found in any disease. This protein has a molecular weight of 90 000 and can chelate a maximum of two iron atoms in the trivalent state (five-odd electrons). The transferrin forms a strong ionic bond with iron in neutral or alkaline solution to give a salmon pink color with an absorption maximum at 470 m $\mu$ . This property has made possible methods for its assay [88]. In vitro the reaction between iron and transferrin is reversible and is dependent on pH. The affinity constant at pH 7 is  $10^7$ . At physiologic pH the ionic iron concentration in the plasma is related to the level of bound Fe-transferrin and the concentration of unbound transferrin. Because of the high molecular weight of the Fe-transferrin it is unlikely that the complex normally leaves the vascular bed in more than trace amounts and thus the iron is presumed to pass in and out of the blood stream in ionized form [89] e.g. after oral iron feeding the plasma iron level increases without a change in the transferrin content. Normally transferrin has a biologic half life of approximately 12 days [90].

The biochemical mechanism for the release of iron from the tissue ferritin to the plasma transferrin has recently been investigated by Mazur and his coworkers. In rat liver slices *in vitro* [91] and in rabbits, guinea pigs, and dogs *in vivo* [92] the enzyme xanthine oxidase was shown to participate in the release of iron from liver ferritin. Tissue hypoxia was induced in all these experiments and was associated with an increase in purines in the liver tissue. Under anaerobic conditions and in the presence of ferritin the purines xanthine and hypoxanthine were oxidized to uric acid by the dehydrogenase activity of xanthine oxidase. In this reaction ferritin acts as an electron acceptor and its iron is reduced to the ferrous state. The ferrous iron can then be removed from the protein moiety by the plasma transferrin.

Thus the tissue oxygen tension levels of xanthine oxidase and xanthine oxidase substrates all may influence the regulation of the iron content of the circulating plasma.

Little is known of the mechanism for release of iron from the plasma transferrin for cellular utilization. On the basis of recent studies with the electron microscope it has been suggested that the immature red cells (erythroblasts) utilize a process called pinocytosis to obtain iron for hemoglobin synthesis by encompassing ferritin molecules directly from macrophages lying adjacent to the erythroblasts [93]. The importance of such a mechanism for incorporation of iron into marrow erythroblasts has not been established. It is known from *in vitro* studies that immature red cells are capable of taking up iron bound to the plasma protein transferrin [94-95]. Also there appears to be a very efficient system in the placenta for the transfer of plasma protein bound iron to the fetal circulation [96]. The reaction *in vivo* between ferric iron and protoporphyrin to form heme appears to be enzyme catalyzed [97]. In rat liver the enzyme is found in the mitochondria [98].

### *Iron Excretion*

The high molecular weight of transferrin and its great affinity for iron probably serve to protect iron from excretion. Normally less than 1 mg is excreted per day in the urine and feces [99]. As the result of menstrual loss the female may lose an average of about 1 mg additional iron per day. The concentration of iron in the bld is 1 to 2 mg per liter; however most of this is reabsorbed so that normally less than 0.5 mg is excreted each day [100]. The urine normally contains less than 0.5 mg iron per 24 hr [101]. In the presence of increased iron stores in man [102] and animals [103] iron excretion is usually slightly increased. It is decreased in states

of iron deficiency. In nephrosis large quantities of the iron transferrin complex may be excreted [104] and the urine may contain more than 15 mg iron per day [105].

### *Iron Absorption*

The normal adult accumulates his total body iron slowly during the first 20 years of life and thereafter remains in iron balance. The amount gaining access to the body by absorption equals the amount lost by excretion (0.5 to 1.5 mg per day). Alterations in excretion are minimal and it is generally agreed that the body content of iron is largely dependent on the amount absorbed. McCance and Widdowson [106] on the basis of their observations on the minimal excretion of iron from the body suggested that the mucosal cells of the gastrointestinal tract have an active role in the control of iron absorption. Hahn [107] from studies with radioactive iron found that iron absorption is not increased until 6 to 7 days after an acute hemorrhage; he suggested that the gastrointestinal mucosa does not increase iron absorption until the body iron stores have been depleted as a result of the accelerated hematopoiesis. He and others [108] found that the antecedent oral feeding of a large quantity of stable iron would block or inhibit the absorption of a dose of radioactive iron administered subsequently and proposed a 'mucosal block' to explain this observation. Granick [79] observed that feeding increasing amounts of iron increases the synthesis of apoferritin and results in the formation of increased amounts of ferritin in the intestinal mucosa. According to Granick, when only minimal amounts of iron are made available from the lumen of the gastrointestinal tract, iron reaches the blood directly through the mucosa. However, if much ferritin is present in the mucosa, it prevents further iron uptake. It was therefore postulated that the amount of iron absorbed depends on the relative state of saturation of the mucosal cells with iron and in turn is related to the level of tissue iron stores. Heilmeyer [109] and Wohler [110] failed to find evidence that the increased ferritin content of the intestinal mucosa reduces iron absorption. When the ferritin content of the mucosal epithelium was maximal, iron absorption continued and hemosiderin continued to increase in the interstitial tissues of the mucosa. If iron is given in excessive quantities [111], the mucosal cells of the intestine are unable to prevent its accumulation in excess of body needs. When more iron is present in the gut, more is absorbed, although the fraction absorbed may be smaller [112, 113].

The concept of the 'mucosal block' fails to explain the excessive absorption and heavy tissue iron deposits found in some subjects after the prolonged ingestion of large amounts of dietary [37, 38] or medicinal iron [5, 20]. Moreover, the diets of patients with primary and secondary hemochromatosis may contain a normal amount of iron, yet its absorp-

tion may be greater than normal [7, 8, 15 18 114-117] Also following experimentally induced hypochromic anemia in animals [118] and in normal subjects [63 64] iron absorption is increased After the anemia is corrected even though the iron stores remain depleted iron absorption reverts to normal In animals with experimentally induced anemia and increased iron stores iron absorption remains elevated [119 120] though it may be slightly depressed in animals when tissue iron stores are increased without an associated anemia [103 113 121] In the circumstances the ferritin content of the duodenum is elevated but the excess ferritin is deposited in the submucosa rather than in the mucosal cells [110]

The normal dietary intake of iron is 10 to 15 mg Less than 10 per cent of this quantity is absorbed through the gastrointestinal mucosa The main sites for absorption of iron appear to be the stomach and duodenum Other areas of the intestine absorb iron if it is present in a soluble form [122 123] Once absorbed the iron is transported via the portal vein blood to the liver In animals it has been shown that the intestinal lymphatic vessels do not transport the absorbed iron [124 125]

Both local intraluminal factors within the gastrointestinal tract and systemic or internal factors may influence iron absorption [126] With the use of  $\text{Fe}^{3+}$  salts it has been demonstrated that the normal adult absorbs 1 to 10 per cent of an oral dose of ferric iron salts if the dose is in the microgram to milligram range [127] With larger than milligram quantities the percentage absorbed decreases in proportion to the amount administered From 5 to 20 per cent of administered ferrous iron is absorbed Usually less than 10 per cent of food iron is absorbed [117 128 129] and the fraction absorbed varies with different foods Administration of a reducing agent such as ascorbic acid promotes the absorption of ferric salts but does not greatly promote absorption of food iron It has been shown experimentally that a low gastric pH will increase iron absorption by promoting the reduction of ferric iron and increasing the solubility of the iron salts Gastric acidity does not appear however to be necessary for absorption of the normal daily iron requirements Subjects with gastric achlorhydria do not show decreased absorption of iron and the addition of HCl to the feeding does not result in an increased absorption [128] The presence of phosphates or other substances capable of forming insoluble ferric or ferrous salts reduces the availability of iron for absorption [127 129 130] The presence of accessory factors that form soluble iron complexes (citrate) increases iron absorption Local secretions within the gastrointestinal tract may influence iron absorption e.g. ligation of the pancreatic ducts increases iron absorption in cats [131] and ethionine induced pancreatic damage is associated with a similar result in rats and mice [132]

The rate of erythropoiesis probably is the most important internal

factor influencing iron absorption [21, 113, 117] Patients with megaloblastic hemolytic and chronic iron deficiency anemias absorb increased quantities of iron, although in the first two groups iron stores are increased Iron absorption is increased in experimentally induced phenylhydrazine anemia in dogs [119] and rats [120] Following acute blood loss increased absorption is not noted for 5 to 7 days which is the time necessary for development of marrow erythroid hyperplasia [107, 113] In man altitude polycythemia will temporarily increase iron absorption [133] and hypoxia produces the same effect in rats [134] These physiologic states of lowered oxygen tension are associated with erythroid hyperplasia Patients with aplastic aregenerative anemias and marrow hypoplasia do not absorb increased amounts of iron, and do not develop siderosis unless they are transfused with red cells Transfusions of whole blood in sufficient quantities to depress marrow activity decrease iron absorption [113] In the absence of erythroid hyperplasia anemia per se and hypoxia do not increase iron absorption The anemia of infection is associated with decreased iron absorption at a time when the tissue iron may be normal or slightly increased [135] Pyridoxine deficiency in swine which is characterized by increased tissue and plasma iron levels and a hypochromic microcytic anemia with erythroid hyperplasia is associated with increased iron absorption [136] The level of the serum iron and the saturation of the plasma transferrin do not appear to influence iron absorption in dogs [137] or man [112] Decreased tissue iron stores in the absence of anemia do not promote [63, 64] increased absorption of iron In rats operative removal of the major quantity of storage iron by partial hepatectomy does not lead to increased iron absorption [133] In the rat increased storage iron produces a moderate decrease in iron absorption [121, 103, 113] or no decrease if anemia is present [120]

In the normal adult in addition to increased marrow activity pregnancy also may serve as a stimulus to increased iron absorption [139, 140] Infants and growing children also absorb increased quantities of iron [141-143] It seems likely that all these stimuli to increased iron absorption are mediated through a humoral agent Although some control of iron absorption seems necessary to restrict iron accumulation in the normal nonanemic adult the iron content of the tissues of the body does not appear to be related in any clear and direct manner to the regulation of iron absorption

#### *Rate of Turnover of Iron*

If it is assumed that the normal adult male has a total body iron content of 4 gm and that he is in iron balance it is possible to estimate the total body iron turnover by measuring quantitatively either iron absorption or excretion If approximately 1 mg iron is absorbed and excreted each day then approximately 9 per cent of the total 4 gm body iron (0.36 gm)

would be turned over per year, and its biologic half life would be about 77 years. Finch recently reported the results of a study on body iron turnover utilizing  $\text{Fe}^{55}$  and red cell sampling over a period of 3 to 5 years [144]. The calculated daily exchange of body iron (absorption or excretion) was 0.61, 0.64 and 1.22 mg in men, nonmenstruating women and menstruating women respectively. This represented a turnover of the total body iron miscible pool (red cell iron plus miscible tissue iron) of 8.3, 10.8 and 20.1 per cent per year. These data demonstrate that the miscible iron pool is appreciably smaller than the total body iron content. The miscible iron exclusive of the red cell iron pool probably does not include all the storage iron. Total body iron turnover studies in mice [103, 145] and ducks [146] have shown a more rapid turnover and the rate of turnover was proportional to body iron content.

After intravenous injection of  $\text{Fe}^{55}$  the plasma radioactivity follows a straight line on a semilog plot for a period of 6 to 8 hr in the normal subject [147]. When the curve is followed longer it deviates from linearity and may be described as a polynomial of at least two exponential terms [148-150]. The rate of turnover of the plasma iron pool may be calculated as the product of the total plasma iron and the fractional turnover rate derived from the initial slope of the curve. In the normal adult the turnover is 35 to 45 mg per day or roughly ten times the total plasma iron.

Fig. 26-1. Metabolic fate of iron. Normal daily rates of turnover through body compartments.

Assuming a mean red cell survival of 120 days and a synthesis of 0.8 to 0.9 per cent of the red cell mass per day, 20 to 25 mg of the total 35 to 45 mg of the rapidly exchangeable iron pool turned over per day is used for the synthesis of hemoglobin. The 10 to 15 mg portion of the labile (marrow) iron pool and the 3 to 4 mg from extracellular fluid, absorption and extramarrow stores are returned to the plasma (Fig. 26-1). This turnover may be increased in hemochromatosis more because of an increase in the total plasma iron than because of an increase in the fractional turnover rate.

The complexity of the  $\text{Fe}^{55}$  decay curve in plasma indicates that the plasma iron is miscible with several other compartments. Some of these are indicated in Fig. 26-1. From the  $\text{Fe}^{55}$  data it is possible to calculate the iron content of the labile iron pool, the quantity of iron that daily re-enters the plasma from this labile pool and the amount of iron leaving the labile pool each day for hemoglobin synthesis. From a knowledge of the iron content of hemoglobin it is possible to calculate the rate of hemoglobin synthesis.

## IRON METABOLISM IN HEMOCHROMATOSIS

In primary hemochromatosis, the quantity of iron in the diet is presumed to be normal. It would seem then that any explanation of the increased iron stores must assume an increased iron absorption at some stage of development of the disease. Quantitative measurements of iron absorption in hemochromatosis have yielded variable results [114-117, 129, 139, 141, 142]. This is probably partially attributable to the fact that iron balance studies utilizing radioactive iron yield variable results in normal subjects and because no strongly positive iron balance is needed to produce the increased iron stores so typical of this disease. The average patient with hemochromatosis has an excess store of 20 gm or more of iron at the time of diagnosis (30 or more years of age). This represents a positive balance of 2 to 4 mg per day over a period of 20 to 30 years or on a diet containing 10 to 20 mg iron per day an absorption of 20 to 30 per cent of the dietary iron rather than the normal 5 to 10 per cent. In a few patients the dietary history points to an increased iron intake secondary to the indiscriminate use of medicinal preparations of iron. These cases are more correctly classified as secondary hemochromatosis.

In a few studies of younger patients with hemochromatosis  $Fe^{59}$  balance techniques have demonstrated increased iron absorption [114-117, 141, 142]. In a recent study [117] in 5 patients an average of 10 per cent of an orally administered dose of radioiron added to a standard test meal was absorbed in contrast to an average of 5 per cent in normal persons. After phlebotomy the disparity between these two groups became more marked and up to 30 per cent absorption was found in patients with hemochromatosis at a time when the serum iron and iron stores were still high. This degree of absorption is more than is seen in patients with iron deficiency anemia or in normal subjects after phlebotomies.

Removal of injected  $Fe^{59}$  from the plasma of patients with hemochromatosis may be slow. Also the plasma  $Fe^{59}$  disappearance curve may show three distinct first-order processes rather than the two usually seen in normal subjects [140]. This suggests that significant amounts of the  $Fe^{59}$  reenter the plasma pool from at least two labile iron pool. Measurements of the slopes of the zero time intercepts permit a determination of the total quantity of iron removed via the marrow and storage each day: the quantity of iron in the labile marrow pool and other storage (liver) pool and the turnover of iron from the labile pool of the marrow used for hemoglobin synthesis. The plasma iron turnover is frequently increased [150, 152, 153] but not the rate of red cell synthesis. Red cell life span is normal. Since there is no increased synthesis of red cells in hemochromatosis increased erythroid activity a known stimulus to

increased iron absorption would not seem to be an etiologic factor in the pathogenesis of the disease

After the intravenous injection of  $\text{Fe}^{59}$  in vivo measurements over the liver show initially a greater than normal accumulation of iron in the liver. This continues for several days and demonstrates the great capacity of the liver to continue to accumulate iron in the presence of excess iron stores [154]

### *Iron Overload Studies in Animals*

Accumulations of iron have been produced in the tissues of experimental animals by various means. In no case has diabetes, cirrhosis, or myocardial damage followed [121, 155-162]. Accordingly there has been a reluctance to attribute the tissue damage in hemochromatosis to iron. However, experimental animals have usually not been fed dietary iron over a sufficiently long period of time to permit the accumulation of iron in amounts comparable to that seen in hemochromatosis. Furthermore, injected iron is distributed primarily in the reticuloendothelial system rather than in the parenchymal cells as in hemochromatosis. In both hemochromatosis and transfusion hemosiderosis (with secondary hemochromatosis) it seems necessary for the body iron content to reach 20 to 30 gm before the clinical picture of classical hemochromatosis makes its appearance. In man, if the bulk of the tissue iron is derived from transfused red cells, more than 50 gm iron may be present without any signs of severe tissue injury such as cirrhosis [163]. In the dog, after the administration of 25 to 35 gm iron intravenously, death results within 5 to 10 months, but no fibrous tissue reaction and no diabetes or cirrhosis is found [164].

## TREATMENT

The treatment of hemochromatosis should be directed at mobilization and removal of the excess tissue iron. Repeated phlebotomies are known to be effective in accomplishing these aims [63-65, 114, 165-173]. Patients with hemochromatosis withstand frequent phlebotomies (500 ml or more of whole blood each 4 to 6 days for many months) without developing more than a mild anemia. This implies that with this bleeding regimen the patients are able to increase their blood production four to sixfold above the normal rate. Failure to maintain a hematocrit above 35 with weekly phlebotomies suggests the presence of a complicating disease such as hepatoma or infection. Even in patients with a moderate degree of cirrhosis, it is usually not necessary to reinfuse the plasma.

In order to have an index of the extent of the iron stores, it is desirable to do a liver biopsy before starting the series of phlebotomies. Since each 1 ml of packed red cells contains approximately 1 mg iron, it is possible to remove only 10 to 15 gm iron per year, and thus in an average patient

the phlebotomies may have to be continued for 2 to 3 years. A gradual fall in the serum iron is usually the first sign of an approaching depletion of the iron stores when this occurs the interval between phlebotomies may be lengthened. A gradual decline in the hematocrit follows indicating a depletion of the iron stores. A repeat liver biopsy serves to confirm the presence of depleted iron stores.

It does not seem necessary to restrict the normal dietary intake of iron or to add phosphates to the diet since the amount of iron absorbed during the period of phlebotomies is small compared with that lost through the bleedings. Because these patients probably absorb an increased amount of the ingested food iron, it may be necessary to continue phlebotomies indefinitely at intervals of 3 to 6 weeks. The chelating agents presently available have no place in the therapy of hemochromatosis because they remove only trace quantities of tissue iron via the urine [174-175].

*Tissue injury (fibrosis of the liver and pancreas) and the clinical manifestations of hepatic, cardiac and pancreatic islet cell insufficiency, skin pigmentation and endocrine disturbances in patients with primary or secondary hemochromatosis strongly suggest a relationship between the iron content of the tissues and their injury. Reversal of many of the symptoms and signs and the lack of progression of the clinical picture of hemochromatosis in patients treated by phlebotomy also suggest that the pathologic features of hemochromatosis may be related to excess tissue iron. Since phlebotomy therapy has been in use for less than 10 years it is too early to predict whether it will materially alter the prognosis. However, experience to date demonstrates that the skin pigmentation decreases, cardiac function improves, liver dysfunction does not progress and the diabetes may be improved as judged by a reduction in insulin requirement. This form of therapy may not alleviate all the manifestations of the disease but it may well prevent further irreversible tissue damage.*

## GENETICS

Hemochromatosis occurs in both adult males and females although it usually occurs earlier in males. Thus it is not transmitted as a sex-linked defect. The disease appears sporadically. Following the initial case report of Frisch [176] on its occurrence in a family, numerous reports of familial cases appeared in the literature. Sheldon [41] evaluated the reported familial incidence in 14 cases but the data appeared reliable in only 5 of the families. Boulin [55] reviewed the data from a total of 27 cases with familial histories reported in 1953. The disease has been reported in 2 or more brothers in more than 25 different families [48, 176-190]. It has been observed in identical twin brothers on three occasions [180, 182, 183]. There are five reports of the disease occurring in successive

generations [42 182 185 186 191] There is one report of the disease occurring in a mother and her identical twin sons [182] and another report of the disease in both the mother and father, and a daughter [185] There are three case reports of the disease occurring as the result of consanguineous matings [186 190 191] In one such family appearance of a severe form of the disease in early adult life in three sisters and a brother [190] suggests the presence of a more severe juvenile form of the disease

The frequent occurrence of an elevated serum iron has been noted in the siblings or children of patients with hemochromatosis [42 186 192] In the study of Debré et al [186] elevated levels were not present in male or female offspring under age 15 nor in female offspring over 15 In males over 15 almost half showed elevated serum iron levels Also hyperpigmentation of the skin and diabetes have frequently been reported in relatives (children parents siblings) of patients with hemochromatosis Increased levels of serum iron and increased iron stores as measured by phlebotomy have been reported in the siblings of patients [42]

An analogy between elevated serum iron levels and hemochromatosis on the one hand and hyperuricemia and clinical gout on the other is perhaps instructive In both disorders the elevated serum concentration of the characteristic chemical substance is encountered much more frequently than the associated disease The onset of the chemical defect at puberty in males has been noted in both disorders Careful studies of inheritance of hyperuricemia have shown that it behaves as a dominant factor when viewed in successive generations but as a polymeric factor when viewed in sibling groups (Chap 21) One could equally well postulate that the genetic factors determining serum iron levels and hemochromatosis are polymeric On this basis one would expect elevated serum iron levels and hemochromatosis to occur in successive generations and in siblings and one would expect a severe and perhaps juvenile form of the disease in individuals inheriting it from both parents in offspring of consanguineous matings

Certain of the family data are also compatible with inheritance as an autosomal dominant trait with incomplete penetrance or even as an autosomal recessive characteristic However it appears unlikely to the author that the quantitative aspects of so complex a process as iron absorption would be determined by a single autosomal gene It is not known whether the genetically determined defect leading to increased iron absorption is in the mucosal cells or in some other body cellular enzyme system which in turn influences the absorptive capacity of the mucosal cells

Further studies of genetic factors in hemochromatosis are needed The combined application of studies of iron absorption and of serum iron

levels in families of patients with hemochromatosis offers a promising outlook for the acquisition of important information

## SUMMARY

1 Primary hemochromatosis is a form of iron storage disease characterized by excessive deposits of an iron hydroxide-protein complex called *hemosiderin* in various organs of the body. It is one of several forms of iron storage disease, and is not associated with known causes of excessive iron absorption such as erythroid hyperplasia.

2 Deposits of hemosiderin occur in liver, heart, the endocrine organs and elsewhere. The signs and symptoms of the disease arise from damage done these organs by the tissue reaction to the hemosiderin deposits. There is a curious metallic slate blue to brown pigmentation of the skin which is primarily due to melanin but also to deposition of hemosiderin. The pigmentation, hepatic cirrhosis and diabetes of the insulin-lack variety form the classical triad of the disease.

3 There is a small daily excessive absorption of iron in primary hemochromatosis. The cause for this is entirely unknown at present. There is no excessive excretion of iron. The net positive balance is only 2 to 4 mg per day. This excessive iron absorption is not associated with the common cause of increased iron absorption which is increased erythropoiesis.

4 There is no increase in intestinal ferritin in primary hemochromatosis nor is there any increase in plasma transferrin, the  $\beta$  globulin protein which normally transports iron. The plasma transferrin is more nearly saturated with  $\text{Fe}^{2+}$  than normally. The turnover of plasma iron is increased.

5 Treatment of the disease if begun early is helpful. It consists of systematic depletion of the iron stores by phlebotomy at appropriate intervals.

6 The disease probably has an autosomal recessive pattern of inheritance which is partially sex limited by virtue of the periodic loss of iron accompanying menstruation. Some families are reported in which the inheritance is more in keeping with a dominant form with incomplete penetrance. Hyperpigmentation of the skin, increased concentrations of serum iron and increased intestinal absorption of iron have been reported in otherwise normal relatives of patient with hemochromatosis indicating partial expression in the heterozygous state.

## Chapter 27

### Periodic Paralysis

---

*Jerome W. Conn and David H. I. Streaten*

Among the many conditions that may be associated with paralysis of the skeletal muscles very few exhibit the intermittency which is the characteristic par excellence of periodic paralysis. Repeated sudden bouts of flaccid muscular paralysis or weakness in persons otherwise enjoying apparently robust health constitute a striking clinical picture which is seldom likely to be confused with other conditions. The disorder has excited interest in the past 70 years out of proportion to its very low incidence because of the expectation that elucidation of its pathogenesis may contribute significantly to the understanding of muscle function in general.

Periodic paralysis may be defined as a disorder occurring usually in young persons characterized by attacks of weakness or paralysis that are spontaneous or in response to stimuli such as administration or endogenous release of salt retaining adrenocortical steroids. Such episodes are separated by periods of apparently normal muscular strength. Relaxation of the muscles predisposes to paralysis; muscular activity has a protective effect. When paralysis is severe it is associated with loss of tendon reflexes and loss of excitability of the muscles to electrical stimuli applied either through the motor nerves or to the muscles directly. Except in a few instances late in the disease there is no clinically evident muscular atrophy. No disturbance of sensation or of consciousness is present. The defect responsible for the condition is genetically transmitted in most cases but also appears to occur sporadically. The abnormality underlying periodic paralysis is now thought to be a disorder in the contractility of muscle resulting from electrolyte changes associated with and probably secondary to intermittent hyperaldosteronism.

#### HISTORICAL LANDMARKS

The literature prior to 1882 contains a few reports of patients who experienced repeated bouts of muscular paralysis which might well have

disease could be associated with periodic paralysis. He demonstrated a greatly increased frequency of attacks during chronic administration of desiccated thyroid to patients with periodic paralysis even in the absence of any known abnormalities of the thyroid gland.

The electrolyte metabolic era was foreshadowed by the report of Biernard and Daniels [12] of a patient with familial periodic paralysis in whom the serum potassium concentration was found to be 13.38 mg per 100 ml (3.4 mEq per liter) during a mild attack and 17.87 mg per 100 ml (4.6 mEq per liter) when the attack had subsided. It was not until 1937, however, that Aitken and associates [13] established conclusively that both spontaneous attacks of periodic paralysis and attacks induced by administration of glucose and insulin were regularly associated with a fall in the level of serum potassium. This observation provided a rationale for the therapeutic use of large doses (12 gm) of potassium salts which they employed with great effect in several attacks. (Previously smaller doses had been given empirically by others [14-15].) Balance studies [16-18] demonstrated clearly that the fall in serum potassium level during attacks was not attributable to a negative potassium balance since urinary losses of this ion did not increase before attacks and fell sharply during them. Studies of the movements of potassium in and out of the extracellular fluid [19-20] suggested strongly that the fall in serum potassium level during attacks results from an excessive internal shift of potassium out of the extracellular fluid probably into the muscle.

The finding that deoxycorticosterone acetate and ACTH would precipitate severe paralytic attacks in patients with periodic paralysis gave rise to the suggestion that the adrenocortical steroids might be implicated in the pathogenesis of this disorder [21-22]. Studies of adrenocortical function in periodic paralysis by Conn et al. [23-24] have confirmed this suggestion by revealing a large increase in aldosterone excretion associated with sodium retention before attacks. The retention of sodium was thought to play an important role in inducing paralysis since patients could consistently be protected from attacks by depleting them of sodium and reducing their sodium intake to a minimum. The significance of these and other more recent observations [25] and their relationship to the observed potassium exchanges and electrolyte composition of skeletal muscle will be discussed in this chapter.

Within the past few years it has become evident that a group of patients previously considered to be suffering from periodic paralysis differ in certain clinical and biochemical respects from patients with the classical syndrome. These patients [26-43] now classified as having *adynamia episodica hereditaria* will be omitted from consideration in the account which follows and discussed in Chap. 28.

A number of excellent reviews of the literature on periodic paralysis

been attacks of what is now known as periodic paralysis. Paucity of the clinical data reported and the nature of some of the recorded observations make the evidence inconclusive, however. It is impossible to be certain for instance that the paralysis in some of these patients was not hysterical in origin [1] or that the disorder which in other patients was associated with malaria [2-4] was actually periodic paralysis.

The first report of a patient who indisputably had periodic paralysis was that of Shakhnovitch [5] in 1882. The patient was a man 44 years of age who had suffered from intermittent paraplegia for 25 years and whose father's death at 54 had been attributed to similar attacks of paralysis. Shakhnovitch also described for the first time the powerful build and splendid general health of the patient between attacks, the induction of attacks by cold, the almost invariable onset of attacks during sleep, the loss of tendon reflexes, and the lack of any disturbance of speech, sensory functions, or control of sphincters during the episodes of paralysis. His patient was considered to be suffering from a new form of neurosis for which he proposed the term *paraplegia spinalis intermittens nervosa*.

The observations of Westphal [6] in 1885 established that paralysis was associated with complete loss of muscular contractility in response to both direct and indirect stimulation with galvanic and faradic current.

In 1890 Goldflam [7] described the frequent occurrence of attacks on one day of the week (Friday in his case), the severe thirst which occurred during paralysis, and the profuse sweating which becomes obvious towards the end of the seizures. He drew attention to the tendency for the paralytic episodes to become less frequent with advancing years. He was also the first author [8] to observe vacuoles in microscopic sections of the skeletal muscles. Goldflam's theory that auto-intoxication is the cause of the malady was generally accepted for 30 years or more. The theory was based on the stubborn constipation experienced by these patients during attacks and on the toxic effect of organic constituents of their urine when injected into rabbits. Thus, while the clinical picture had been well delineated and the underlying histopathologic changes in the skeletal muscle had been described in great detail by the end of the nineteenth century, little progress had been made in tracing the pathogenesis of periodic paralysis.

Between 1900 and 1937 the main contribution to an understanding of periodic paralysis was the introduction of the experimental approach to the disease. This followed the discovery by Kramer [9] that the precipitation of attacks by the ingestion of large meals was due to their high content of carbohydrate. This observation was independently confirmed by Shinosaki [10] who was the first to use administration of glucose for the experimental induction of paralytic attacks. In company with other authors, Shinosaki also confirmed Kitamura's [11] report that Graves

Fig. 26.1 Age of onset of attacks in representative series of familial periodic and thyrotoxic periodic paralysis and in adynamia episodica hereditaria.

to be more severe and more apt to end fatally in males than in females [48 56 62 63].

**Geographic Distribution and Racial Incidence** Although the disease is rare it has been reported from many parts of the world. Most of the patients have been Caucasians from Europe and North America. There have been a number of reports from Russia, Japan, India, and Brazil. No cases have been described among the Chinese or the Negro people.

have been published. Among the best are those of Goldflam [7, 44], Taylor [45], Schmidt [46], Janota and Weber [47], Dalinghaus [48] and Talbott [49].

## CLINICAL ASPECTS

### *Incidence*

**Age.** The age of onset of paralytic episodes has a wide range of variation, the extremes being 1 to 2 years [50] and 56 years of age [9, 51]. Attacks frequently begin during infancy in patients belonging to the group of *adynamia episodica hereditaria* (see Chap. 28) and during the third or fourth decades of life in patients with thyrotoxicosis [52-55]. After excluding these two groups from consideration, it appears that attacks have begun between the ages of 7 and 21 years in 93 of 100 patients described in the literature. These features are shown in Fig. 27.1 which gives the distribution of the ages at which paralytic episodes first occurred in the published reports of periodic paralysis (familial, sporadic and thyrotoxic) and of *adynamia episodica hereditaria*. The similarity in age of onset in familial and sporadic cases of periodic paralysis is in good accord with other evidence that the two conditions are identical except for the evident lack of hereditary transmission in the sporadic group. The striking differences between periodic paralysis and *adynamia episodica hereditaria* on the other hand support the view that these are different entities.

Several reports show a striking constancy in the age of onset of paralysis among most members of an affected family, e.g. 7 to 8 years in the family of Biemond and Daniels [12], 12 to 16 years in one of Mankowsky's families [56] and 17 to 19 years in MacLachlan's [57] and Khan's [58] families.

The severity and frequency of attacks usually increased to a maximum at about 20 years of age, remained substantially unchanged for 10 years or more, and became less severe and less frequent, especially in females, from about the age of 30 to 40 years, frequently disappearing some time between the ages of 32 and 73 years [7, 13, 17, 46, 56, 59]. A number of patients did not follow this usual benign course. Some persons continued to experience severe attacks in middle life or old age [7]. In a few of the larger families progressive muscular atrophy with permanent weakness or paralysis supervened in a number of the elderly patients [12, 60, 61].

**Sex.** In most families with periodic paralysis the disorder occurred more frequently among males than among females. The preponderance of males was slight in some families (Table 27.1a) and overwhelming in others (Table 27.1b). Among patients with thyrotoxicosis, males have been exclusively affected (Table 27.1c). The vast majority of sporadic cases have also been males.

Both in familial and in sporadic cases attacks of paralysis have tended

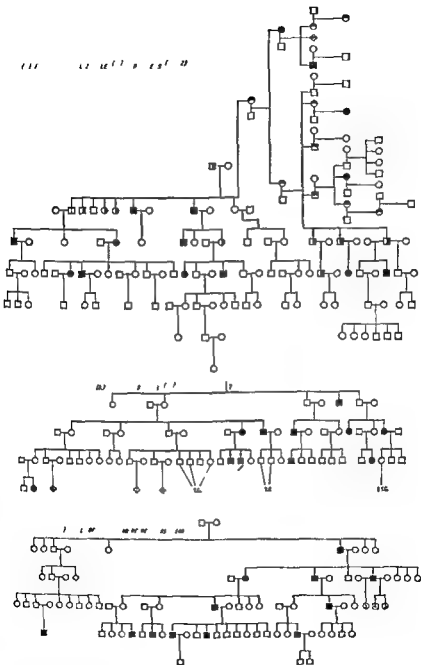

Fig. 2. Genealogy of periodic paralysis in three families (See Fig. 1 for explanation of symbol.)

TABLE 27.1 SEX INCIDENCE OF OVERT PERIODIC PARALYSIS IN A FEW OF THE REPORTED FAMILIES

| Type of case   | No. of cases |         | Reference |
|--|--------------|---------|-----------|
|  | Males        | Females |           |
| a Familial euthyroid cases with no marked male preponderance | 8            | 6       | [10]      |
|  | 6            | 5       | [44]      |
|  | 6            | 5       | [4]       |
| b Familial euthyroid cases with marked male preponderance    | 11           | 1       | [10]      |
|  | 11           | 3       | [50]      |
|  | 5            | 0       | [47]      |
|  | 8            | 0       | [8]       |
|  | 8            | 1       | [1]       |

|  | 4            | 0       | [53]      |
|  | 1            | 0       | [54]      |
|  | 1            | 0       | [118]     |
|  | 6            | 0       | [87]      |
|  | 1            | 0       | [55]      |
|  | 3            | 0       | [94]      |

and Dalinghaus [48] has drawn attention to the absence of the condition in the tropics

#### Condition between Attacks

Between attacks most patients have been free of symptoms and have had no abnormal physical findings. The one striking feature that many authors have commented upon has been the robust physique and the appearance of unusually good muscular development in most of the males [5, 9, 17, 46, 47, 64-74]. Even those of asthenic habitus or short stature [70] usually had an athletic build. The muscular size has at times suggested pseudohypertrophic muscular dystrophy, and muscular strength was sometimes less than normal [46]. More frequently, however, the strength of the muscles was as much increased as their size, so that the patients were good athletes who enjoyed a rugged outdoor life [47, 61, 75].

It has been reported that Chvostek's sign was present between attacks [76, 77] and disappeared during attacks in three patients [77] and that it remained positive in a fourth [76]. Goldflam [7] found reduced electrical excitability of the muscles between attacks in two patients, but Janota and Weber [47] considered that the electrical excitability of the muscles to direct and indirect stimuli was slightly increased between attacks.

#### Associated Disorders

In some patients the clinical features of thyrotoxicosis have been present, with enlargement of the thyroid gland and laboratory evidence

due to the high carbohydrate content of such a meal [9] administration of glucose has been used as an experimental method of precipitating attacks [10] Insulin alone will induce attacks [87] and the administration of both glucose and insulin is a very effective method of precipitating attacks [13 16 21 23 24 59 86 89 93-96]

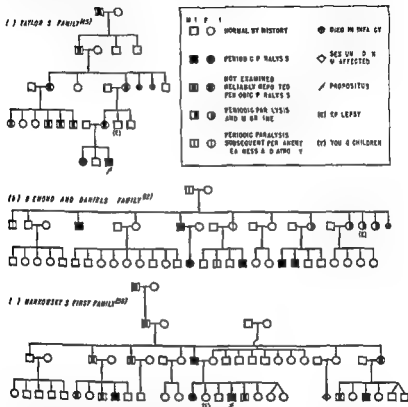

Fig 27.3 Genealogy of periodic paralysis in three families

**Rest and Muscular Relaxation** Rest especially following vigorous exertion appears to play an important role in precipitating attacks. Thus many writers [5 7 9 10 12 14-16 18 45-47 49 52 53 57-60 62 64 65 68 70-73 78 80 82 85 88 90 92 94 96-110] have mentioned that the severe attacks usually occur at night in the early hours of the morning or when the subject is at rest during the day. Conversely patients frequently learn that they can abort mild attacks (walk them off) by exercise [15 18 41 44 53 59 70 100 102]. That rest may have local effects on the muscles of these patients has been shown by the observation that paralysis may supervene in an immobile limb while active limbs escape [44 70 75]. The strong tendency for attacks to recur on the same

of hyperthyroidism (elevated basal metabolic rate (BMR), increased uptake of radioactive iodine by the thyroid and raised serum protein bound iodine (PBI) concentration) In these persons paralytic episodes started after the onset of thyrotoxicosis Shinosaki [10] and other Japanese authors have emphasized that the thyroid is frequently enlarged without evidence of hyperfunction of the gland but these observations were made before the advent of modern methods of appraisal of thyroid function

Various *neurologic disorders* may occur together with periodic paralysis *Migraine* is the most important of these A history of migraine in patients with periodic paralysis and in their relatives has been described frequently [12, 15, 47, 56, 57, 59-61, 68, 70, 71, 73-80 cf also 81] Migrainous headaches and paralytic attacks may occur in the same patient at different times or simultaneously and the occurrence of a headache has even seemed to protect some patients temporarily from an attack of paralysis acting as a type of 'equivalent' for attacks of periodic paralysis [52, 60] Gardner [63] MacLachlan [57] and Holtzapple [60] have all described the occurrence of headaches for several years followed in the same patient by the onset of paralytic attacks and cessation of the headaches Of the 14 patients with periodic paralysis in Holtzapple's family [60] the disease was transmitted through a parent with paralytic attacks in 10 instances and through a parent who had frequent sick headaches in the remaining 7 instances (Fig. 27.2a) If migraine and periodic paralysis constitute different modes of expression of the same abnormal gene as some of the evidence might suggest (see Genetics further on) then the incompleteness of penetrance in this family—and possibly in some of the others in the literature—would be more apparent than real *Epileptic seizures* have been reported frequently in patients with periodic paralysis [5, 56, 72, 82] and in some of their unaffected relatives (Fig. 27.3) *Progressive muscular atrophy* on the other hand apparently develops mainly in patients who have experienced paralytic episodes for many years and not in unaffected relatives [12, 59-61] (Figs. 27.2a and 27.3b)

### *Factors Which Induce Attacks*

Four groups of stimuli are known to precipitate attacks of paralysis in patients with the disease

**"Stresses" of a Wide Variety** These have included infectious diseases [6, 57, 60, 83] surgical and accidental trauma [62, 83, 84] emotional excitement anxiety or anger [10, 15, 16, 22, 45, 59, 70, 85] severe muscular exertion [10, 45, 68, 78, 80, 86, 87] menstruation [15, 88] and exposure to cold [5, 46, 47, 57-59, 89-91]

**Increased Utilization of Carbohydrate** That the ingestion of a heavy meal particularly in the evening tends to precipitate an attack has long been recognized [7, 15, 16, 58, 59, 65, 68, 71, 72, 91, 92] Drinking beer has also been incriminated [63, 86, 91] Since the effects of a heavy meal are

overcome by actively exercising the affected muscles [5 7 10 16 41 53 59 70 100 102]

The muscles may be painful during attacks [90] but the pain may often be relieved by a change of position [52] Several authors have been struck by the swelling of the affected muscles which gave them a firm rubbery consistency during attacks [5 57 59 69 71 83 85 89 105] Measurement of the affected limbs has shown that the apparent swelling has frequently been associated with an increase in circumference during paralysis [69 72 90 110 113] Contraction of the affected muscles on direct or indirect stimulation with galvanic or faradic current is reduced or completely abolished in proportion to the severity of the paralysis [4 6 7 13-15 68, 87 106] The deep tendon reflexes are reduced or abolished but the abdominal and cremasteric reflexes may be unaffected There is no loss of any sensory modality and no impairment of mental faculties or consciousness during even the severest of attacks

The myocardium may be affected along with the skeletal muscles during paralytic seizures Oppenheim's [106] original description of transient bradycardia and cardiac dilatation with the appearance of a systolic murmur at the apex believed to result from mitral insufficiency during attacks has been confirmed in part or entirely by many observers The bradycardia which is typical of the fully developed attack [68 90 95 106] is preceded by tachycardia before and early in the attack [14 46 47] The clinical evidence of transient cardiomegaly [10 46 66 68 106] has been verified by x ray [21 77 113] Elevation of blood pressure [10 46 66 110 114 116] and arrhythmias [10 44 60 103] have been reported during attacks

Gastrointestinal features of the attacks include occasional nausea and vomiting [46 66 77 78 95 102] and constipation bowel movements occurring seldom if ever during severe attacks [7 12 46 66 71 80 100 116] The possibility that these findings might result from loss of normal intestinal peristaltic motility was suggested to Dalinghaus [48] by the reports that bowel sounds are absent during attacks [46 80]

Changes in the intake and urinary output of water or both have frequently been described Thus severe thirst and increased imbibition of fluids may occur before or early in attacks [7 10 12 16 47 72 106 116] In contrast whether fluid intake is increased or decreased urine is seldom passed spontaneously during an attack [12 14 45-47 66 69 71 74 77 78 89 90 100] When the urine volume has been measured in relation to the fluid intake positive water balance has been found during paralysis [49] Severe sweating may occur during paralytic seizures and usually tends to usher in the phase of recovery [6 7 10 12 14 46 47 57 63-72 84 90 100 106]

**Phase of Recovery** The commencement of improvement is frequently evident clinically by the occurrence of a bout of severe sweating and by

day of the week, usually on Sundays or Mondays [7 10, 15, 65 68 73, 90] may be related to indulgence in more relaxation and a greater intake of food during the week end, or in some cases to increased athletic activity in the presleeping hours

**Drugs** Drugs which have been used to stimulate attacks include epinephrine [10 16, 59, 87, 95, 110-112] deionized thyroid [10 15 87] parathyroid extracts [10] adrenocortical extracts [90] deoxycorticosterone acetate [21 25] ACTH [22] 2 $\alpha$  methyl 9 $\alpha$  fluorohydrocortisone [24] and ammonium glycyrrhizinate [25]

### *Prodromal Symptoms*

While many patients are unaware of an impending attack until they awake paralyzed in the early hours of the morning some patients have experienced recognizable prodromata. The commonest appear to have been sensations arising from the muscles, described variously as aches and pains or cramps in the muscles [6 10, 14 16, 53 68 90, 100 109] stiffness or a tight feeling [15 57 71 86 93] and fatigue [9, 10 52 60 72 98]. Other patients have noticed numbness tingling and other paresthesias [6, 55 60 71 75 78] apprehension irritability or excitability [65 67 72], and an increase in thirst preceding attacks [9 16 45, 71, 72]

### *Paralytic Attacks*

Paralytic attacks may occur from once in a lifetime [47] to once a week [7 10, 15 65, 68 73 90] there may even be nightly attacks for 10 years [71]

Abortive attacks may last for less than an hour while attacks with complete paralysis usually last 6 to 24 hr. More severe seizures may endure for 1 or 2 days while Donath [84] and MacLachlan [57] have both recorded authentic instances of attacks lasting 8 days

**General Description of Attacks** In attacks which develop while the subject is awake weakness and then paralysis usually appear first in the lower limbs then in the arms trunk and neck in that order [6 7 14]. More characteristically patients are awakened in the early hours of the morning with widespread flaccid paralysis which renders them helpless

The diaphragm the muscles of the face and mouth and those involved in speech and swallowing are spared with rare exceptions such as in Putnam's [65] patient who in some of his severe seizures could move only his lips and eyes. On the rare occasions when death has ensued it has usually occurred during an attack involving the muscles of respiration [57] (see Mortality and Pathologic Findings further on in this chapter)

Many attacks are only partial involving a few muscle groups a single extremity or two limbs on the same side of the body or opposite sides—i.e., hemiplegia or paraplegia [90]. Minor attacks of localized weakness may occur during the day it is these attacks which can frequently be

sistent and is of doubtful significance. On two occasions endogenous creatinine clearance showed a slight reduction of questionable significance on the day of an attack [117-122].

*Urinary creatine* has been reported increased between attacks [95] to fall before the day of paralysis [21] and to rise during attacks [18-100].

*Urinary excretion of phosphorus* tends to be reduced in attacks roughly in parallel with urinary potassium [16]. An increased output of phosphorus after the attacks [16-123] is associated with no increase in the output of calcium and is therefore probably derived from muscle rather than from bone [123].

*Excretion of calcium and magnesium* has been found to be increased during attacks [10-18].

Changes in urinary excretion of sodium potassium chloride nitrogen uric acid pepsinogen 17 hydroxycorticoids 17 ketosteroids and aldosterone will be considered in detail in a subsequent section (see Metabolic Studies further on).

#### BIOCHEMICAL CHANGES IN BLOOD

The fall in serum potassium [12-13-16-21-23-49-55-59-74-94-96-98-119] and the rise in serum sodium concentration [23-24] will be discussed more fully later (see Metabolic Studies below).

Serum inorganic phosphorus falls for a few hours. This was reported first by Aitken et al [13] and was confirmed by many others [16-21-74-95-115]. The fall per se is probably of little or no importance in paralyzing the muscles since the infusion of sodium phosphate does not prevent paralysis [115].

Blood cholesterol concentration usually rises during attacks of paralysis [119a].

No change has been reported in blood pH [69], blood urea [13-103], serum calcium [10-13-18-21-80] or serum magnesium [13-18-21] although Yoshimura [124] found a rise in serum magnesium during attacks. Goss et al [103] reported that the cephalin flocculation and thymol turbidity tests, icteric index and serum total proteins were normal in their patient.

#### ELECTROMYOGRAPHIC AND CHEMICAL CHANGES IN MUSCLE

##### *Electromyographic Findings*

These have been described in detail in two patients with periodic paralysis by Lichler Jantz and Jung [96]. In the intervals between attacks the biphasic muscle action potentials were found to be normal in duration and shape. Rapid faradic stimulation however caused rhythmic fluctuations in the amplitude of the action potentials. These were more pronounced than the rhythmic changes seen in normal subjects indicating

the onset of diuresis [24, 46, 49 66] Muscles which were paralyzed first are usually the last to recover their function strength returning first to the neck and arms Recovery is usually complete in 1 to 3 hr from its commencement but it may take a day or more Pain stiffness or soreness in the muscles may persist for a day or two after the attack [60, 71 108] Patients customarily lose 1 to 3 kg in body weight because of the diuresis which occurs during recovery [117]

## LABORATORY FINDINGS

### ROUTINE LABORATORY FINDINGS

**Urinalysis** Transient mild proteinuria [9, 10 12, 46 47, 56] glycosuria [9 10] acetonuria [10 47, 118] and cylindruria [118] have been described during the attacks

**Hematologic Changes** Goldflam [8] reported a consistent neutrophil leukocytosis with eosinopenia during the attacks and lymphocytosis with eosinophilia after the attacks These findings have been confirmed by other authors [14 56, 66] Sugimoto [92] described the occurrence of lymphopenia during attacks of paralysis in a thyrotoxic patient

**Electrocardiogram** The ECG is normal between attacks and shows the changes characteristic of hypokalemia during episodes of paralysis viz flattened or inverted T waves particularly in the chest leads depression of RS-T segment and the occurrence of large U waves giving rise to the appearance of a prolonged Q T interval [19 21 24, 47 56 59 71 74 80 96 102, 108 109 119] Grob et al [19] have pointed out that the hypokalemic changes in the ECG are more severe in these patients than in normal persons at the same level of serum potassium

**Cerebrospinal Fluid** It may contain a slightly increased amount of protein [80 103] but shows no abnormality in pressure or cell count [49, 62 103] The potassium concentration in the cerebrospinal fluid is unchanged [95 103] or may be lowered [120] during attacks of paralysis

**Radiologic Abnormalities** These are restricted to the evidence of enlargement of the heart during the attacks [21 77 113] Cerny et al [114] have reported bony bridging of the sella turcica in four out of five affected members of a family with periodic paralysis

**Other Tests** Electroencephalography has shown no abnormalities [108] The BMR is elevated during paralysis contrary to the expectation in a paralyzed person [71 88 121] Gastric juice has been reported to contain little or no acid during attacks [15 48 77]

### BIOCHEMICAL CHANGES IN URINE

**Urinary excretion of creatinine** has been reported by Mitchell et al [16] to be low before attacks and high after attacks A slight fall in creatinine output [117] has been observed during attacks the finding was incon-

significantly different from the findings in normal subjects in whom KCl administration was consistently followed by increased uptake without subsequent loss of potassium from the forearm tissues. In most instances improvement in muscular strength following KCl administration lagged behind the rise in plasma potassium concentration but rapid improvement occurred when potassium loss from the tissues started i.e. in the second and third hours after KCl had been given. These findings together with the observation of increased potassium uptake by the tissues even in mild attacks associated with no fall in plasma potassium concentration suggested that abnormal uptake of potassium by the muscles is more important than the fall in plasma potassium in inducing muscular weakness. This suggestion is in good agreement with the conclusions of Fichler et al [96] based on electromyographic evidence. It receives further support from the observation that during recovery from attacks there was loss of potassium from the forearm which was hastened by increasing muscular activity as recovery progressed.

Zierler and Andres [20] made similar observations on the arteriovenous differences of potassium in two of the patients with familial periodic paralysis investigated by Grob et al [19]. These authors suggested that the nocturnal onset of spontaneous attacks and their usual spontaneous recovery later in the morning might be due to an exaggeration of the normal diurnal rhythm of potassium influx into the tissues at night and potassium efflux from the tissues during the day.

### *Muscle Function Studies*

The investigations of Grob et al [19] have shown that the muscle end plate became resistant to the depolarizing effect of intraarterially injected acetylcholine during bouts of weakness. Attacks were also accompanied by reduced propagation of muscle action potentials across the muscle following a single stimulus to the ulnar nerve. It was concluded that the decreased responsiveness of the muscles to nervous stimulation during attacks might be due to the development of resistance to the depolarizing action of acetylcholine normally released from the motor nerve endings. Since an increase in the ratio  $[K_{\text{transcellular}}]/[K_{\text{intracellular}}]$  ( $[K_{\text{out}}]/[K_{\text{in}}]$ ) causes hyperpolarization in experimental animals it was suggested that a similar change in this ratio might produce hyperpolarization of the motor end plate during attacks of periodic paralysis with resulting loss of muscular responsiveness to nervous stimulation. Similarly, hyperpolarization of the entire muscle membrane might bring about the observed reduction in the spread of the excitation wave to other parts of the muscle fiber.

The studies of Grob et al [19] confirmed the observation of Merton (reported by Mc Ardle [41]) that in patients with periodic paralysis the force of muscular contraction was reduced more rapidly and more severely than the amplitude or the propagation of the muscle action potentials.

that the muscle was abnormal even in the unparalyzed state. After the administration of glucose and insulin, but before paralysis supervened progressive widening of the action potentials occurred to two or three times their normal duration. Usually there was lengthening of the latent period between stimulus and response. As weakness advanced to complete paralysis there was progressive increase in the latent period, while the action potentials became more prolonged in duration and reduced in amplitude, until they could no longer be elicited shortly before all voluntary contractility of the muscle was lost. Rapid faradic stimuli induced a progressive increase in the rhythmic fluctuations in amplitude of action potentials until even before paralysis supervened the motor response to indirect faradization disappeared.

Eichler et al [96] have pointed out that the abnormalities in muscle action potentials started before paralysis of voluntary movement had taken place and before any other objective changes such as the fall in serum potassium level or alterations in ECG at a time when the only change was a subjective feeling of weakness. During the process of recovery from attacks the abnormalities in the electromyogram (EMG) were still present when the serum potassium had returned to normal or elevated levels and these abnormalities were restored to normal only after further delay. These findings indicate that the abnormalities in muscle action potentials do not result from the lowered level of serum potassium. Eichler et al suggested therefore that the EMG changes might reflect a movement of potassium into the muscle during paralysis.

#### *Potassium Exchanges between Plasma and Tissues*

Grob et al [19] have studied arteriovenous differences in plasma potassium concentration in three patients between and during attacks of weakness and paralysis. Their results indicated that the uptake of potassium from the arterial plasma by forearm tissues after administration of insulin or of epinephrine was significantly greater in the patients with periodic paralysis [19] than in the normal persons studied [19]. In 15 spontaneous attacks of weakness which followed evening meals high in carbohydrate content the patients showed significant increases in potassium uptake from the arterial blood into the tissues as compared with the potassium uptake by their tissues before the attacks. That the muscle and not the bone or skin was the site of the increased uptake of potassium during the attacks is suggested by the finding that the weakened contractions which could still be elicited during the attacks resulted in an increase in venous plasma potassium. This increase was four times as great as prior to the attack and twice as great as in normal persons following much stronger muscular contractions. The administration of KCl during attacks of paralysis caused initial uptake of potassium by the tissues followed paradoxically by a loss of potassium from the forearm.

After 44 days low sodium intake following total desalting with distilled water (10 mEq NaCl per day) (Tissot et al.)

Initial 4+ = mild hypokalemia 3+ = moderate hypokalemia 2+ = severe hypokalemia 1+ = mild hypokalemia

high sodium content of the muscles probably predisposed the subjects to paralysis since reduction of the sodium concentration by the desalting rendered the muscles immune to the paralytic effects of glucose and insulin and of mineralocorticoids (see under Sodium further on).

Paralyzed or weakened muscle consistently showed higher potassium concentrations (82-85-81-82 mEq per kg) than muscle sampled between attacks (75-74 mEq per kg). These results suggest that an acute shift of potassium may have taken place into muscle during the process of becoming paralyzed—a conclusion in good accord with the other evidence described above [19-21, 108]. In such paralyzed muscle the sodium concentration remains high and the potassium concentration is increased so that the concentration of (Na + K) becomes consistently higher

following nervous stimulation. For this reason it was postulated that the most important defect in periodic paralysis might lie in the contractility of the muscle itself rather than in transmission of the nervous impulse to the muscle. Again the hyperpolarization of the entire muscle fiber resulting from increase in  $[K^+]/[K^+]$  might be incriminated as an important defect in the muscular contractility, since actomyosin is kept in the uncontracted state by high membrane potentials [126].

### *Chemical Composition of Skeletal Muscle*

Evidence obtained by chemical analysis of muscle obtained by biopsy lends support to the more indirect evidence of potassium shifts in periodic paralysis described above. Jantz [21] reported that the concentration of potassium in muscle was increased at the height of an attack of paralysis to 710 mg per 100 ml (182 mEq per kg), and fell within half an hour of the recovery of normal muscle function to an approximately normal figure 360 mg per 100 ml (92 mEq per kg). Vastola and Bertrand [108] found that the onset of paralysis was associated with the movement of 120 mEq of potassium into each kilogram of muscle solids together with an increase of the water content especially in the extracellular fluid phase (i.e. the chloride space) of the muscle. The change in water content neutralized the effect of the potassium shift on the concentration of potassium in the sample of wet muscle which was unchanged by the occurrence of paralysis. Since the calculations of Vastola et al [108] show that the concentration of potassium in intracellular water actually fell from 196.5 to 190 mEq per liter when paralysis supervened their contention that the resting membrane potential had increased during paralysis is difficult to accept. However the increased quantity of potassium which these authors found within the muscle cells might be an even more important inhibitor of the association of actomyosin than an increased concentration of potassium [126].

More recent determinations of the electrolyte composition of muscle in periodic paralysis carried out in the authors laboratory (Table 27<sup>2</sup>) are in general agreement with the results of Jantz [21]. Between attacks of paralysis the concentration of potassium in the muscle was low (70 mEq per kg) probably indicating chronic potassium deficiency. The sodium concentration (46 mEq per kg) was considerably elevated as is usual in chronic potassium deficiency [127]. In fact the muscle composition between attacks closely resembled that seen in primary aldosteronism. "Desalting" the patient with diuretics reduced the sodium concentration in the muscle to 34 mEq per kg without materially affecting the potassium concentration. Since the sodium concentration in the muscle was high between attacks and was increased only slightly or not at all when paralysis was induced it seems likely that the supervention of paralysis did not involve a further shift of sodium into muscle. On the other hand a

high sodium content of the muscles probably predisposed the subjects to paralysis since reduction of the sodium concentration by the desalting rendered the muscles immune to the paralytic effects of glucose and insulin and of mineralocorticoids (see under Sodium further on)

Paralyzed or weakened muscle consistently showed higher potassium concentrations (82-85-81-82 mEq per kg) than muscle sampled between attacks (75-74 mEq per kg). These results suggest that an acute shift of potassium may have taken place into muscle during the process of becoming paralyzed—a conclusion in good accord with the other evidence described above [19-21 108]. In such paralyzed muscle the sodium concentration remains high and the potassium concentration is increased so that the concentration of (Na + K) becomes consistently higher

(130 137, 127 129 mEq per kg) than in the unparalyzed state (121 108 mEq per kg) and higher than in normal subjects and patients with primary aldosteronism. Lales et al [120] have confirmed the presence of raised intracellular sodium and reduced intracellular potassium concentrations between attacks and the finding of a higher intracellular potassium concentration during an attack. As suggested by Conn et al [23, 24] it is possible that the excessively high  $Na + K$  content of the muscles consequent upon an acute inward shift of potassium is the cause of the paralytic attacks: since sodium and potassium have similar effects on the association of actomyosin [128] and since the actomyosin system is sensitive to the total amount of intracellular  $Na + K$  and not to their molar concentration [126].

#### EXCHANGEABLE SODIUM AND POTASSIUM (Table 27.3)

In four patients with periodic paralysis, Streeten and Conn [75] have found the exchangeable body sodium ( $Na$ ) to be high normal or elevated between attacks (46.6, 48.3, 51.3 and 51.4 mEq per kg) the normal range for  $Na$  at 24 hr in the same laboratory is  $38.5 \pm 2.9$  (s.d.) mEq per kg. In

24-hr values using  $Na^{22}$  and  $K^{42}$  separately

two of these patients exchangeable body potassium ( $K$ ) was determined and found to be 35.3 and 41.5 mEq per kg these values are slightly low for young males (normal mean  $49.3 \pm 6.4$  (s.d.) mEq per kg [129]). The high  $Na$  results may reflect the paucity of body fat in these lean athletic individuals but the slight lowering of  $K$  is all the more remarkable for the same reason. The patient studied by McArdle and Merton [130] had an exchangeable body potassium (43.4 mEq per kg) that was considered normal though it was well below the value obtained in their one normal control (51.3 mEq per kg). The ratio  $Na/K$  in the authors' patients (1.44 and 1.20 Table 27.3) was extraordinarily

high for lean muscular males normal values being 0.74 to 0.94 for males [131]. Such elevation of the ratio is seen also in primary aldosteronism in conditions associated with edema and in states of severe chronic debility and inanition. It has never been reported in apparently robust young males in the absence of periodic paralysis or primary aldosteronism.

### METABOLIC STUDIES

#### *Potassium*

**Serum Potassium Concentration** Between attacks the serum potassium concentration is normal in some patients but in others it may tend to be low. In one patient [70] for instance the fasting level of serum potassium was below 4.0 mEq per liter on 26 out of 28 days between attacks and was 3.3 mEq per liter or lower on 10 of these days. Repeatedly lowered serum potassium concentrations between attacks are evident also in the protocols of the patients reported by Talbott [49] and by Gass et al. [103]. A rapid and profound fall in serum potassium concentration, frequently to as low as 1.5 or 1.7 mEq per liter is one of the most consistent findings in attacks of periodic paralysis in patients with the familial sporadic or thyrotoxic forms of the disease [12 13 16 21 23 49 55 59 74 94-96 98 119]. The occurrence of hypokalemia during spontaneous and induced attacks is seen in Figs. 27-4 to 27-11. Several authors have drawn attention to the variability in the level of serum potassium at which paralysis occurs [16 17 74].

**Fate of the Disappearing Serum Potassium** In 1938 Allott and McArdle [16] and Pudenz et al. [90] independently showed by the balance technique that the fall in serum potassium could not be attributed to losses of potassium in the urine or stool. On the contrary urinary potassium excretion fell strikingly during the attacks as many observers have subsequently confirmed [17 18 21-23 49 103 119]. In the absence of an increased external loss of potassium the fall in serum potassium was attributed to an internal shift from the extracellular fluid into some other compartment presumably intracellular. This conclusion was supported by the electromyographic and muscle composition studies described above.

**Changes in Urinary Potassium** In attacks of paralysis induced by glucose (150 gm) and insulin (20 units) or by the potent synthetic mineralocorticoid 2 $\alpha$  methyl 9 $\alpha$  fluorohydrocortisone (1 mg p.o.) the urinary excretion of potassium declined simultaneously with the fall in serum potassium as shown in Fig. 27-4. In the spontaneous attacks of paralysis too the reduction in urinary potassium output accompanied but never preceded the fall in serum potassium concentration. Reduced urinary excretion of potassium is therefore probably entirely a secondary phenomenon consequent upon the fall in serum potassium which results from internal sequestration of potassium in the muscles or elsewhere. It

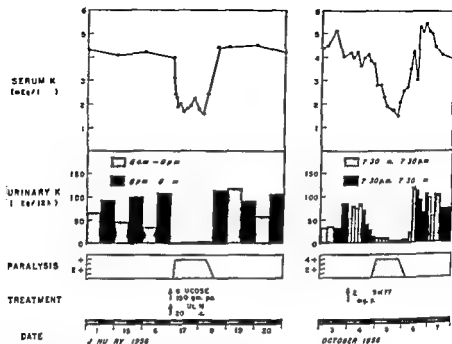

Fig 27-4 The time relationships between potassium changes in serum and urine during attacks of periodic paralysis induced by (1) glucose and insulin and (?) 2 $\alpha$  methyl 9 $\alpha$  fluorohydrocortisone

seems important that muscle function often begins to return before serum potassium values rise significantly. This phenomenon is preceded by sodium diuresis. After the end of the attacks diuresis of potassium usually occurred for 1 or 2 days.

### Sodium

**Sodium Retention** Severe attacks of paralysis either spontaneous or induced are usually preceded by sodium retention resulting in a positive balance of 100 mEq or more. Figure 27 5 shows the urinary output of sodium over a period of 8 weeks in a patient who experienced several spontaneous attacks of weakness and paralysis during this time. These included one spell of complete quadriplegia (designated as 4+ paralysis in the figure), three of severe paralysis of the limbs (3+ paralysis), one of weakness of the arms and legs (2+), and several of mild weakness of arms or legs (1+). Most of the severe attacks were preceded by sodium retention for 1 to 3 days. Sodium retention was greater and more consistent in the attacks induced by glucose and insulin (Fig 27 6) ■ methyl 9 $\alpha$  fluorohydrocortisone (Fig 27 7) DC\ ammonium glycyrrhizinate and ACTH [20] than in the spontaneous attacks. Unlike the reduction in potassium excretion which coincided with or followed the onset of

hypokalemia and paralysis the sodium retention preceded the paralytic spells and is therefore likely to be of greater significance in the pathogenesis of attacks [24]. A negative sodium balance usually occurred for 1 to 2 days after the end of the attacks and was sometimes of considerable magnitude. Sodium retention during attacks has been reported also by Pudenz et al [90] and Terrebee et al [18] and has been confirmed more recently by Eales et al [120] and de Graeff and Brocker [132]. An increase in exchangeable body sodium has been demonstrated to result from the sodium retention which preceded an attack of paralysis induced by 2 $\alpha$  methyl 9 $\alpha$  fluorohydrocortisone [24].

**Serum Sodium Concentration** The serum sodium tended to rise shortly before or during most seizures of severe paralysis or both in the three patients studied by Conn, Streeten et al [117]. This change was probably of little consequence in affecting muscle power but might have stimulated the thirst and oliguria which have frequently been commented on during attacks.

**Effects of Restriction of Sodium Intake** Remarkable protection from spontaneous and induced attacks was found to result from restriction of the daily intake of sodium to 10 mEq or less combined with initial desalting procedures (using diuretics such as chlorothiazide, mercurials and acetazoleamide) and quantitative replacement of the potassium losses resulting from the diuretics used [23-26]. Thus in contrast with the frequent spontaneous attacks on a normal sodium intake of 176 to 190 mEq per day shown in Fig. 27.5 there was only one bout of 3+ paralysis on the fourth day of a 23-day period on a 10 mEq sodium diet which was not combined with desalting. No attacks occurred in over 6 weeks on an 8 mEq sodium diet after initial administration of acetazoleamide and mercaptopimerin. During the latter period of 44 days two separate attempts to induce paralysis with 2-day courses of glucose and insulin administration and one attempt with 2 $\alpha$  methyl 9 $\alpha$  fluorohydrocortisone (see Fig. 4 in Conn et al [23]) were quite unsuccessful whereas previously and subsequently these stimuli never failed to induce paralysis in the same subject. Similar results [26] have been obtained in another patient who was readily paralyzed on the second day of receiving repeated doses of glucose (150 gm) and insulin (20 to 35 units) on a normal sodium intake (200 mEq per day). On an intake of 5 mEq per day however even without preliminary desalting this patient was protected from the paralytic effect of the same course of glucose and insulin administration. These observations on the protection afforded by a low sodium intake have been completely confirmed in two other patients studied by the authors including one with thyrotoxicosis [25] in the first of two studies by Eales et al [120] and in the less severe of two patients reported in brief by de Graeff and Brocker [132]. It is not clear whether the incomplete protection afforded by a low sodium diet in the other studies

of Lales and de Graeff et al might have been attributable to inadequate sodium depletion or to failure to replace the potassium lost by the action of the diuretics used

### *Chloride*

Changes in the urinary chloride excretion followed closely the changes in the urinary output of sodium. There was reduced urinary excretion before and during attacks and diuresis at the end of the attack [18, 23-29]. Like the serum sodium, the serum chloride concentration tended to rise before and during attacks, and this change was associated with approximately reciprocal changes in  $\text{CO}_2$  combining power [18, 25].

### *Water*

**Total Body Water** In many of the severe spontaneous and induced attacks observed in three patients on a constant diet [20] the sodium retention which usually preceded paralysis was associated with gain in weight signifying retention of water. An increase in body weight before attacks was observed previously by Neel [90] who attributed the gain in weight to the fall in urine volume which he and others [69] had observed. On the other hand, Ferrebee et al [18], Talbott [49] and Danowski et al [119] found negligible changes in body weight before attacks. The weight gain in the patient studied for the longest period of time by Conn et al [23-25] was greatest before the attacks which followed administration of the potent salt retaining substances DCA (3.2 kg) and ammonium glycyrrhizinate (2.2 kg). It was smaller before attacks which occurred after 2 $\alpha$  methyl 9 $\alpha$  fluorohydrocortisone (1 kg), glucose and insulin (1.1 kg and less than 0.5 kg) and spontaneously (0.3, 0.8, 0.2, -0.2, 0.1, -0.3, -0.5 kg). Poor correlation between the magnitude of weight change and the severity of the attacks suggested that an increase in total body water was of little or no importance in the genesis of the paralytic seizures. Support for this suggestion was derived from the finding that no paralysis resulted from the administration of pitressin tannate in oil despite an increase in the body weight of 3.2 kg in 3 days (see [20]). It may have been important that the severe retention of water induced by the pitressin tannate was associated with a negative sodium balance of 133 mEq (excluding fecal losses). This natriuresis was similar to that which follows the administration of pitressin to normal subjects, in whom it has been shown to be associated with reduction in aldosterone output [133-135]. There are a few reports of paralytic seizures which occurred after the administration of water [17, 136] but other authors [89, 103, 137] have failed to confirm that water loads even as large as 4-11 liters would precipitate an attack.

**Changes in Fluid "Compartments"** Ferrebee et al [18] and Danowski et al [119] found that paralytic attacks were associated with no signif-

icant change in extracellular fluid volume Danowski et al [119] observed a rise of 17 per cent in the plasma volume during attacks however Talbott [49] found plasma and extracellular fluid volumes to be increased in his patient as much as during attacks of paralysis In a single determination by Streeten and Conn [75] the bromide space between attacks was greater than normal Whether this implied an increased extracellular fluid volume or abnormal permeability to chloride of the tissues (muscle for example) which are usually relatively impermeable to this ion was not determined McArdle and Merton [130] found that the cellular water content was decreased to 21.4 liters in a patient with periodic paralysis between attacks compared with a normal value of 30.5 liters

Inadequacy of the available evidence makes it difficult to be certain of real changes in the internal distribution of body water in periodic paralysis although the published results suggest an expansion of plasma volume with conflicting evidence bearing on changes in the extracellular and intracellular compartments If such changes were aggravated before attacks one would expect them to result in a fall in the hematocrit In studies of three attacks it was found by Ferrebee et al [18] that the hematocrit remained unchanged early in the attacks but showed a downward trend during attacks from a mean value of 42.5 per cent at the onset to 39.7 per cent at the end of the attacks Since these changes did not precede the paralysis and since the downward trend in hematocrit during paralysis continued until 24 hr after complete recovery in the two patients in whom it was recorded these observations suggest that the development of paralysis was not associated with any significant internal shift of body water

### CHANGES IN ADRENOCORTICAL FUNCTION

#### *Steroid Excretion*

Apart from reports of occasional 17 ketosteroid values [108-114] no systematic studies of steroid excretion had been reported in patients with periodic paralysis prior to the work of Conn Streeten et al [20] The urinary excretion of 17 hydroxycorticoids [138] 17 ketosteroids [139] and aldosterone (estimated by bioassay as described by Streeten et al [140]) is correlated in Fig. 27.5 with the changes in serum potassium concentration and urinary sodium output in a number of spontaneous attacks observed in one patient In Fig. 27.6 a similar correlation is shown in four attacks induced by glucose and insulin in the same patient and in two others with sporadic periodic paralysis The aldosterone values shown in Fig. 27.6 were obtained using the chromatographic method of Neher and Wettstein [140a] as modified by Louis [122]

**Urinary 17 Hydroxycorticoids** A definite increase in the output of 17 hydroxycorticoids occurred on the first and second days of paralysis

Fig. 27-5 Serum potassium and sodium and steroid excretion in patients with spontaneous attacks of periodic paralysis.

In this and subsequent figures illustrating metabolic data, severity of paralysis is indicated as follows: 4+ = complete quadriplegia; 3+ = severe paralysis of the limbs; 2+ = weakness of arms and legs; 1+ = mild weakness of arms or legs.

Electrolyte (e.g., sodium) intake is indicated by the dotted line, and urinary output is plotted from the base line upwards, so that when urinary output exceeds intake, the output column rises above the dotted line depicting intake.

The cross-hatched areas (Nos. 1 to 6) indicate the duration of major attacks of paralysis.

in the most severe spontaneous attack (Fig 27 5 No 4) and on the day before and the day of the next most severe spontaneous attack (No 6). An increase in 17 hydroxycorticoids was also seen in the two severe attacks (Fig 27 6 Nos 7 8) induced by glucose and insulin. The 17 hydroxycorticoid output was higher on the day of each of these attacks than on any other day of the study. The mild attacks, both spontaneous (Fig 27 5) and induced (Fig 27 6 No 9) were accompanied by no demonstrable change in 17 hydroxycorticoid excretion.

**Urinary 17 Ketosteroids** The 17 ketosteroids showed an undoubted increase in the two severe attacks [20] (Fig 27 5 Nos 4 6). Moreover even the less severe attacks were always associated with an increased output of 17 ketosteroids on the day of the attack (Nos 3 5) or the day immediately before (No 2) or after (No 1) the attack. Again the fact that the 17 ketosteroid output at the time of the attack was in every instance the highest excretion reported for 2 to 14 days before and after each attack suggests that these changes are significant despite the relatively wide day to day fluctuation in 17 ketosteroids in this patient. The increase in excretion of 17 ketosteroids *before* attacks (Nos 2 6) suggests that adrenal hyperactivity or whatever change in steroid metabolism caused this augmentation of 17 ketosteroid output might have been concerned in the causation and was certainly not the result of the paralytic attacks. This interpretation is strengthened by the observation that a severe attack of complete paralysis which occurred after the administration of the potent nonsteroidal sodium retainer ammonium glycyrrhizinate (a triterpene) was associated with no significant change in 17 ketosteroid output. Thus the 17 ketosteroids were 20.6, 18.9 and 18.1 mg before administration of the triterpene, 20.0 and 18.4 mg on the first and third days of its administration, 17.1 and 19.1 mg on the 2 days of the attack, and 17.0 mg on the following day. The evidence suggests therefore that the increased output of 17 ketosteroids before or during attacks of paralysis is a characteristic feature of the metabolic events leading to spontaneous seizures but one which plays no essential role per se in inducing paralysis. Cerny et al [114] in the protocol of one of their patients with familial periodic paralysis recorded an increase in the urinary 17 ketosteroids from 5.8 mg per day between attacks to 17.3 mg per day on the day of an attack. This observation is in agreement with those described above.

**Urinary Aldosterone Output.** The urinary excretion of aldosterone-like material was estimated by bioassay before, during and after five of the spontaneous attacks (Fig 27 5 Nos 2 to 6). In every instance a large increase in excretion of aldosterone-like substance occurred on the day before and usually also on the day or days of paralysis. Excretion of salt-retaining steroid was normal (less than 3  $\mu$ g per day) on several of the days between attacks but was not infrequently increased on two days

between attacks when a great increase in aldosterone output occurred sharp sodium retention also occurred (Sept 26 and Oct 7, 1955) In addition one of these days (Oct 7) was followed by the only reduction in serum potassium concentration below 4 mEq per liter observed among

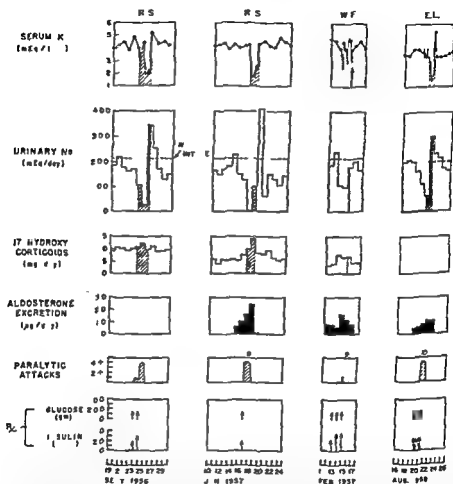

Fig 27-6 Serum potassium and urinary sodium and steroid excretion in attacks of periodic paralysis induced by glucose and insulin. Symbols as in the legend for Fig 27-5

52 determinations obtained between attacks in this patient. These findings may therefore have represented an 'abortive spontaneous attack.'

The attacks induced by glucose and insulin in the three patients (Fig 27-6) were also associated with increased urinary output of aldosterone (measured chromatographically in these studies). The more

modest rise in aldosterone output in these induced attacks might simply reflect the differences in technique or might indicate that the spontaneous attacks were really associated with far greater adrenocortical hypersecretion than occurred after glucose and insulin. Bearing in mind the obvious limitations of the bioassay [140-141] one is probably justified in attributing this difference to technical factors until further evidence to the contrary has been adduced. Eales [136] has confirmed the finding of an elevated aldosterone output during two spontaneous attacks.

Since the increased output of adrenocorticoids in the urine before and during attacks involved three different steroids and since paralytic attacks were associated with no obvious changes in hepatic or renal function it seems reasonable to conclude that increased adrenocortical secretion was the cause of the increased urinary excretion of these metabolites. This conclusion receives support from the evidence of the biologic effects of increased adrenocorticoid output.

#### *Biologic Effects of Increased Adrenocortical Steroid Output*

**Electrolyte Metabolism** Since the augmented output of aldosterone correlated reasonably well with the sodium retention and the decreases of serum potassium (Fig. 27-5) there is reason to believe that hypersecretion of aldosterone might have been the cause of these electrolyte effects. The rise in serum sodium associated with the attacks [23-24] was probably also attributable to hypersecretion of aldosterone. The urinary output of potassium was reduced (Fig. 27-4), rather than increased as would have been expected normally during greatly increased aldosterone secretion. Thus a fundamental defect in periodic paralysis (unavailability of potassium for urinary excretion during attacks) is again evident. It is significant that administration of mineralocorticoids to such patients results in the same abnormal pattern of renal excretion of electrolytes.

**Organic Metabolism** Changes in protein metabolism during paralytic attacks have been reported by Conn, Streeten, et al. [25]. Figure 27-7 shows the urinary nitrogen output before, during, and after 14 attacks of paralysis in one patient (R. S.). The duration of attacks is indicated by crosshatching. Fecal losses of nitrogen were not estimated except in the first attack (Oct. 1, 1950) in which the occurrence of a slightly negative nitrogen balance on the first and third days of the attack is shown. Urinary losses of nitrogen were so great on the day of or after each of the spontaneous attacks or both, however, that they frequently exceeded total nitrogen intake. The attacks induced by glucose and insulin (Nos. 10-11) and by 2 $\alpha$ -methyl-9 $\alpha$ -fluorohydrocortisone (No. 12) were also associated with a negative nitrogen balance, but no increase in urinary nitrogen output occurred in the attacks induced by DCA (No. 13) and ammonium glycyrrhizinate (No. 14). The steroid 2 $\alpha$ -methyl-9 $\alpha$ -fluoro-

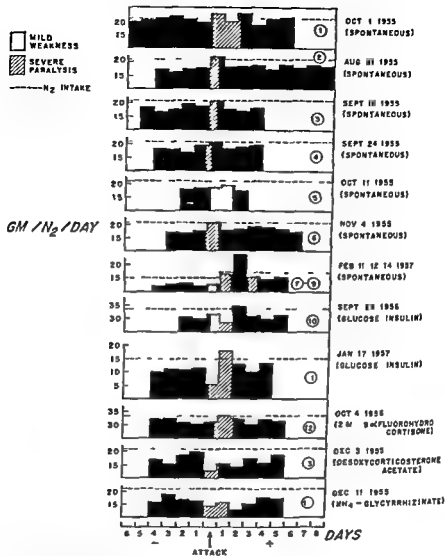

Fig 27.7 Changes in urinary nitrogen in a patient during 14 attacks of periodic paralysis. The data are plotted as in Fig 2.5

hydrocortisone has sufficient glucocorticoid potency to increase urinary nitrogen excretion when given to normal subjects in doses as low as 0.5 mg by mouth [142]. The increased nitrogen excretion observed in the patient with periodic paralysis given twice this dose (Fig 27.7 No 12) therefore might well have resulted from the glucocorticoid activity of the steroid administered and does not imply an increased endogenous release of glucocorticoids. DCA and ammonium glycyrrhizinate are both known to possess potent mineralocorticoid activity and to be practically

devoid of glucocorticoid activity. The absence of increased nitrogen excretion in the severe attacks which followed their administration therefore suggests that the excessive adrenocortical secretion of a glucocorticoid (probably hydrocortisone) in the spontaneous attacks neither played an essential role in the genesis of muscular paralysis nor resulted merely from the stress of the seizures.

Uric acid excretion was increased from a mean control level of 0.93 gm per day to 1.05 to 1.54 gm per day on at least one of the days in each of six spontaneous paralytic attacks studied in the same patient [25]. On the only day between attacks when the urinary uric acid excretion exceeded 1.05 gm per day there were also sodium retention, a fall in serum potassium to 3.9 mEq per liter, and increased 17-hydroxycorticoid excretion with increased aldosterone output on the preceding day, suggesting that an abortive attack was taking place. The increased uric acid excretion presumably reflected the effects of increased adrenocortical secretion of hydrocortisone.

**Other Effects of Adrenocortical Hyperactivity** Urinary ammonia was greatly increased on the day of paralysis in four spontaneous attacks and in one attack which occurred probably spontaneously on the second day of prednisolone therapy (following spontaneous increase in aldosterone secretion the day before the attack). The same phenomenon occurred during attacks induced by an upper respiratory infection and by administration of glucose and insulin. 2 $\alpha$ -methyl 9 $\alpha$ -fluorohydrocortisone (DCA) and ammonium glycyrrhizinate [25]. Increased urinary ammonia probably resulted from increased mineralocorticoid activity since it was seen in the attacks which followed administration of DCA and ammonium glycyrrhizinate and is known to occur in primary aldosteronism where there is no increase in 17-hydroxycorticoid excretion [122]. The resemblance of this increased urinary excretion of ammonia to that which occurs under the influence of excessive aldosterone secretion was further manifested by the striking phenomenon of its persistence through the second day of three severe attacks of paralysis when urinary pH was increased above 7.0.

*Urinary pepsinogen excretion* increased on the day of or after each of three spontaneous attacks: one attack induced by ACTH gel, one which followed an upper respiratory infection, two induced by glucose and insulin, and one precipitated by 2 $\alpha$ -methyl 9 $\alpha$ -fluorohydrocortisone [25]. A rise in the urinary excretion of pepsinogen may result from increased renal clearance of pepsinogen in response both to adrenocortical stimulation [143] and to infusion of hydrocortisone [144]. It has been encountered in primary aldosteronism [144a]. Increased urinary pepsinogen excretion in periodic paralysis therefore presumably results from the increased adrenocortical secretion of hydrocortisone or of aldosterone or both.

### SIGNIFICANCE OF THE INTERMITTENT ADRENOCORTICAL HYPERSECRETION

It has been shown that both spontaneous attacks and attacks induced by glucose and insulin are accompanied by a transiently increased secretion of adrenocortical steroids. This phenomenon, which frequently starts before paralysis supervenes, constitutes a characteristic feature of the paroxysms and is not merely the consequence of the "stress" of paralysis (see discussion under Organic Metabolism above).

#### *Elevation of Urinary 17-Hydroxycorticoids*

This probably results from increased secretion of hydrocortisone since the usual results of such an increase are readily recognizable: negative nitrogen balance [25] (see under Organic Metabolism above), greater excretion of uric acid [20], mildly elevated FBS [10, 20, 47, 56, 114], leukocytosis [8], lymphopenia [92] and eosinopenia [8]. These changes are quite mild, however. The administration of glucocorticoids in amounts equivalent to or even greater than the adrenocortical output of hydrocortisone which would be estimated to occur before or during these attacks (probably never more than twice the normal adrenocortical output of 25 to 35 mg hydrocortisone daily) does not cause paralysis [22]. For these reasons and because severe paralysis may result from procedures which do not increase glucocorticoid activity in the body (e.g. administration of DCA and ammonium glycyrrhizinate) there is little doubt that excessive secretion of hydrocortisone plays no essential role in the genesis of paralysis.

#### *Increased Output of Urinary 17-Ketosteroids*

This increase is more consistent than the augmentation of 17-hydroxycorticoid excretion. It may result from increased adrenocortical production of adrenal C<sub>19</sub> steroids, from increased hepatic formation of 11-oxygenated 17-ketosteroids from glucocorticoids, or from increased testicular secretion of androgens. In the absence of further evidence which might be obtained by chromatographic fractionation of the elevated urinary 17-ketosteroids, it is difficult to interpret the significance of this change. There can be little doubt that while this change too is an integral part of the metabolic events inherent in the genesis of paralysis it plays no direct role in paralyzing the muscles.

#### *Increased Output of Aldosterone*

This is the steroid change which most consistently precedes and accompanies spontaneous paralytic seizures. Furthermore, an increase in the salt-retaining, aldosterone-like activity in the body is the only known factor which is common to almost all, if not all, of the means by which

paralysis may be induced: emotional upsets [145] infections surgical and other physical trauma [146] increased rate of carbohydrate utilization resulting from glucose and insulin administration (see Urinary Aldosterone Output above) and the administration of ACTH [147 148] adrenocortical extract DCA  $2\alpha$  methyl  $9\alpha$  fluorohydrocortisone and ammonium glycyrrhizinate. There are therefore strong reasons for believing that a transient rapid increase in aldosterone production plays an important role in the pathogenesis of paralysis.

This evidence is strengthened by the observation in four patients [24 25] that the paralytic effects of glucose and insulin were completely abolished by feeding a low salt diet. Most if not all of the metabolic effects of aldosterone are known to be abolished by sodium restriction. This procedure may ameliorate or entirely reverse many of the abnormal features of severe primary aldosteronism [149]. Additional confirmation of the pathogenic role of transient hyperaldosteronism in precipitating attacks has been adduced by the administration of a spiro lactone (SC8100) to these patients. Adequate doses (500 mg q 6 h p o) of this drug which is known to antagonize the effects of liberated aldosterone [150 151 152] prevented the sodium retention which was otherwise always associated with the administration of glucose and insulin to one patient. In another patient with severe periodic paralysis associated with thyrotoxicosis the same spiro lactone protected the individual from paralysis during 3 days of glucose and insulin administration although 1 or 2 days of the latter treatment had previously paralyzed him consistently [25].

#### NATURE OF THE RELATIONSHIP BETWEEN TRANSIENT HYPERALDOSTERONISM AND PARALYSIS

Consideration of the evidence bearing on the following questions may serve to clarify the nature of the defect in periodic paralysis.

1 *Is the hyperaldosteronism due to an excessive stimulus to aldosterone production or to an excessive response by the adrenal gland to a normal stimulus?* Excessive secretion of aldosterone has been observed repeatedly in spontaneous attacks which were preceded by no known psychic or physical trauma and by no acute dietary excess of carbohydrate (the patient being on a constant diet in the sheltered environment of the metabolic ward). These observations imply either that the adrenal gland was unduly sensitive to normal day-to-day stimuli or that some defect in the hypothalamus or elsewhere was resulting in intermittent excessive release of glomerulotropin [153]. If the former alternative were correct it would be anticipated that the release of aldosterone would have been greater in these patients than in normal subjects following the same stimulus. Administration of glucose and insulin to normal young adult males has revealed increases of 17 hydroxycorticoids 17 ketosteroids and

aldosterone which were very similar to the changes seen in the patients with periodic paralysis [122]. Thus it appears that the increased carbohydrate utilization which results from the administration of glucose and insulin is a stimulus to adrenocortical hypersecretion in normal subjects. In addition, Conn et al [117] have found that the increase in urinary aldosterone resulting from sharp restriction of dietary sodium in normal people is seen also in patients with periodic paralysis. Thus the adrenal glands of patients with periodic paralysis probably possess no inherent abnormality in their responsiveness to physiologic stimuli. The implication is that intermittent hyperaldosteronism in periodic paralysis arises from an extraadrenal abnormality which stimulates hypothalamic release of glomerulotropin or from a primary defect in the hypothalamus characterized by intermittent "spikes" of glomerulotropin release.

It may be of some interest that glucose (150 gm) and insulin (20 units) in amounts which induced quadriplegia in a patient with severe periodic paralysis have been administered to a patient with severe primary aldosteronism due to an adrenocortical adenoma [7a]. No muscular weakness ensued. Aldosterone excretion did not increase but instead, fell from 100 to 30  $\mu$ g per day and the preexisting sodium retention was not aggravated in this patient in response to glucose and insulin. These findings indicate that the aldosteroma which proved to be present in one adrenal gland was not responsive to the physiologic stimuli to which normal adrenal glands respond. Certainly the responsiveness of the adrenal glands in patients with periodic paralysis to glucose and insulin administration and to other physiologic stimuli appears to be normal. On this basis as well as upon the basis of what scanty autopsy evidence is available one can eliminate with reasonable certainty, the likelihood that adrenocortical tumors are involved in the pathogenesis of periodic paralysis. The conclusion seems justified that in this disease there occurs periodically an excessive stimulus which results in the release of abnormally large amounts of aldosterone and that this stimulus arises by virtue of an abnormality which is not localized in the adrenal gland.

2 *Is there a primary defect in muscle membrane permeability?* Evidence can be marshaled for and against this proposal. Patients with periodic paralysis are regularly paralyzed by doses of 2 $\alpha$  methyl 9 $\alpha$  fluoro hydrocortisone (1 mg given once p.m.) or deoxycorticosterone acetate (12.5 mg b.i.d. intramuscularly). Such quantities of mineralocorticoids cause smaller decreases of serum potassium and no paralysis when administered to normal subjects. Figure 27.8 shows that a single dose of 2 $\alpha$  methyl 9 $\alpha$  fluorohydrocortisone (1 mg p.o.) produced a far greater fall in serum potassium in two patients than in two normal male subjects of comparable age and on the same diet. This suggests that an abnormality of membrane permeability to potassium is present in periodic

paralysis With respect to sodium however there is no evidence for the presence of a membrane defect in the kidney since the degree of sodium retention following this dose of 2 $\alpha$  methyl 9 $\alpha$  fluorohydrocortisone was not abnormal either at the time of onset of paralysis in the two patients

Fig 27.8 Effects of 2 $\alpha$  methyl 9 $\alpha$  fluorohydrocortisone on serum concentration and urinary excretion of sodium in normal subjects and in patients with periodic paralysis

or over the subsequent 3 days when compared with the changes in normal subjects. The paradoxical fall in urinary potassium excretion in the patients does not necessarily indicate the presence of a membrane defect since it might be explained by the more rapid and profound reduction of serum potassium as the result of more rapid sequestration of potassium presumably in the muscles in these individuals than in normal subjects (see Changes in Urinary Potassium above).

Immersion of one arm in cold water for 20 to 35 min may cause severe

weakness of the muscles of that arm [41, 59, 71, 90] without a concomitant fall in the serum potassium concentration in the weakened limb [41, 59]. This observation led McArdle [41] to conclude that the muscles themselves were abnormal in periodic paralysis and to postulate that the defect lay in the muscle membrane permeability. The abnormalities in muscle electrolyte composition (see under Chemical Composition of Skeletal Muscle, above) and other evidence confirm the conclusion that the muscle itself is abnormal but they do not eliminate the possibility that this abnormality might be secondary to a remote cause, such as a prior, chronic excess of aldosterone reaching the muscle through the circulating blood. It is quite possible, too, that cooling might inhibit the association of actomyosin in the muscles of the patient as it has been shown to do in vitro [126]. In the presence of abnormal electrolyte composition of the muscle this inhibitory effect of cooling might be sufficient to weaken or paralyze the muscle. Whatever the exact nature of the local effect of cold on muscle function is it might be significant that exposure to cold has precipitated paralysis in patients with primary aldosteronism [154] in whom composition of the muscles is deranged in the same way as it is in periodic paralysis (Table 27.3). The finding that in periodic paralysis the influx of potassium into muscle is not exaggerated but normal between attacks [20] may be cited as further evidence against any intrinsic defect of the muscle membrane.

On the other hand one could postulate a possible sequence of events based upon a primary abnormality with respect to potassium in bone muscle, or both in which (1) sequestration of potassium slowly increases to a critical value (2) this excites release of aldosterone, (3) the latter in the presence of adequate sodium produces a simultaneous increase in intracellular sodium and (4) abnormal muscle function or paralysis results from excessive intracellular concentration of cations.

#### OTHER HORMONAL CHANGES

##### *Follicle Stimulating Hormone (FSH)*

Cerny et al [114] have reported in a patient with familial periodic paralysis that urinary excretion of FSH was greatly increased to 80 and 400 rat units a day during two attacks and fell to below 20 rat units a day on two days between attacks. The low level between attacks was confirmed in two other patients.

##### *Thyroid*

Thyroid function has been normal in patients with sporadic periodic paralysis who had no clinical evidence of thyrotoxicosis [75]. In those patients who have had the clinical features of thyrotoxicosis associated with periodic paralysis there has been adequate laboratory evidence of hyperthyroidism in the form of elevated BMR, increased serum PBI

concentration and increased 1, 2, and 24 hr uptake of  $I^{131}$  by the thyroid gland [53, 55, 94, 116, 155]. The muscular disorder in these patients is similar to that found in the more usual euthyroid patients in that attacks are predominantly nocturnal, show a predilection for resting muscles, are always associated with a profound fall in serum potassium level, and can be prevented by a low sodium diet as well as by administration of the aldosterone antagonist SC8109 [155]. These observations and the findings that attacks of paralysis in patients with thyrotoxicosis are associated with an increase in aldosterone output [156] suggest that increased secretion of thyroid hormone may induce adrenocortical release of aldosterone. This possibility, the existence of which has yet to be demonstrated conclusively, would be consistent with the report of Shinosaki [10] that bouts of paralysis occurred with greater frequency in patients with periodic paralysis who were treated with large doses of desiccated thyroid. Since an increased output of ACTH, glomerulotropin, and FSH has been demonstrated or inferred before or during attacks, it might be speculated too that an excess of yet another tropic hormone, thyroid stimulating hormone, might be responsible for the thyrotoxicosis in these patients. There is at present no direct evidence to support this possibility.

## PATHOGENESIS

The available evidence is insufficient to establish conclusively the nature of the primary defect in periodic paralysis. However, the hypothesis to be advanced here is consistent with what evidence there is and might be useful in indicating where future studies would be expected to be fruitful.

Measurement of adrenal steroid excretion during spontaneous and induced attacks of paralysis has provided indirect and admittedly tenuous evidence that the primary defect in periodic paralysis might consist in the occurrence of intermittent excessive stimuli to the secretion of adrenocorticoids, particularly aldosterone. The possibility that these stimuli arise from the hypothalamus would be supported by the reported occurrence of periodic paralysis in patients with concomitant manifestations of hypothalamic disorders [51, 118, 157].

Intermittent mildly excessive secretion of aldosterone over a period of many years between attacks probably produces a slightly negative potassium balance by increasing urinary losses of potassium, as McArdle [47] has observed at least temporarily in a patient who ingested a diet containing low normal amounts of potassium. Thus, like all other losses of potassium from the body, would be expected to cause depletion of potassium in the skeletal muscle and its replacement by sodium. The shifts would produce the observed abnormalities in muscular electrolyte composition as well as in exchangeable body sodium and potassium.

between attacks for which no other explanation is at present available. In this way chronic low grade more or less intermittent excesses of aldosterone secretion probably set the stage in the skeletal muscle (and perhaps in the myocardium and even the smooth muscle as well) for the more severe sudden increases in aldosterone secretion which result from physical or psychic trauma ingestion of unusual amounts of carbohydrate foods, or perhaps 'spontaneous' hypothalamic discharge of glomerulotropin. Such sudden marked increases in the secretion of aldosterone as well as of hydrocortisone and other adrenocorticoids occur immediately before attacks of paralysis. The effects of these increased rates of steroid secretion may be recognized in the negative nitrogen balance increased uric acid excretion eosinopenia leukocytosis sodium retention and increased urinary excretion of pepsinogen and ammonia none of which probably plays any direct role in the pathogenesis of paralytic attacks. That paralytic attacks occur mainly at night and in resting muscles may result from the additive effects of rest and an excess of circulating aldosterone both promoting the rapid uptake of potassium by the muscles of which there is strong evidence during the attacks from a number of sources [19, 20, 21, 25, 96, 103]. That aldosterone does have a direct effect on skeletal muscle increasing its potassium content and reducing its sodium has recently been shown in acute experiments on mice [158] which await confirmation. The contrary opinion that aldosterone decreases muscle potassium and increases muscle sodium has been based largely upon indirect evidence from the effects of chronic aldosterone excess where renal wastage of potassium was probably responsible for the potassium deficiency and sodium excess in the muscles.

Under the influence of rest and acute hyperaldosteronism the influx of potassium into the muscle cells appears to be more rapid than the loss of sodium so that the muscles come to contain too large an amount and frequently too high a concentration of sodium plus potassium as has been shown in biopsy studies during paralysis (see under Chemical Composition of Skeletal Muscle above). It is probably the increased amount of sodium + potassium in the muscle cells which interferes with the association of actomyosin [126, 128] and in this way causes paralysis. Hyperpolarization of the muscle end plate and membrane resulting from the sudden rise in intracellular potassium concentration and the fall in serum potassium concentration might play a less important part in paralyzing the muscle. The fall in serum potassium concentration and in urinary excretion of potassium during the attacks probably result from rapid uptake of potassium by the muscle.

### DIFFERENTIAL DIAGNOSIS

When repeated attacks of flaccid muscular paralysis have occurred upon awakening in a young subject who appears to have been in perfect

health between attacks the only conditions which might be confused with periodic paralysis are *adynamia episodica hereditaria* and *hysteria*. *Adynamia episodica hereditaria* is readily differentiated by the clinical differences enumerated in Chap 28 and by the absence of a fall in serum potassium during an attack. *Hysteria* may be recognized by its characteristic psychologic features by the usual presence of sensory changes the persistence or even accentuation of reflexes the predilection for females and the retention of the muscular responses to electrical stimulation.

Less severe attacks causing weakness only may present more difficult diagnostic problems. The presence of muscular atrophy early in the course of the disease would favor a diagnosis of *progressive muscular atrophy* of spinal origin or one of the primary muscular dystrophies since in those few familial cases of periodic paralysis which manifest this sequela muscle wasting occurs only late in the course of the disorder [12]. The weakness of *myasthenia gravis* is characteristically least in the mornings and increases during the day it involves facial and ocular muscles early frequently lacks the intermittency of periodic paralysis responds dramatically to the administration of neostigmine and is not associated with hypokalemia though it may be improved by the administration of KCl. The myotonic components of *dystrophia myotonica* and *myotonia congenita* are absent in periodic paralysis. *Peripheral neuritis* produces sensory as well as motor impairment.

In a first attack of paralysis several other possibilities have to be excluded such as *cerebral lesions* (vascular accidents tumor etc) *spinal lesions* (tumor syphilis poliomyelitis) and *lesions of peripheral nerves* (polyneuritis Landry's paralysis Guillain Barré syndrome and diabetic neuropathy). The cerebrospinal fluid and concomitant neurologic abnormalities will usually enable these conditions to be differentiated from periodic paralysis without difficulty.

*Primary aldosteronism* even when associated with repeated attacks of paralysis is distinguished from periodic paralysis by the occurrence of hypertension and the persistence of hypokalemia between attacks.

## MORTALITY AND PATHOLOGIC FINDINGS

Talbott [49] has drawn attention to the fact that in about 10 per cent of the patients reported in the literature death has occurred during attacks of paralysis. A fatal outcome has been seen in sporadic as well as in hereditary cases and a particularly high rate of mortality has been recorded in some families such as Holtzapple's [60] in which six patients died in attacks of paralysis (Fig 27 2). The causes of death when related to the disease have been mainly *respiratory paralysis* [56 57 60 115] *respiratory infections* [46 60] *inhalation pneumonia* [10] *cardiac failure* [71] *shock* [51] and *excessive therapeutic venesections* [10 46 79].

*Autopsies* have been reported on a number of patients who died in or

out of attacks [7 10 16 46, 57, 60 79 90 114, 159] The changes of Graves' disease were seen in the thyroid of a patient who had hyperthyroidism [10] and evidence of cardiomegaly and venous congestion in patients who died in cardiac failure [114] Shinosaki [10] considered that the histologic appearance of the parathyroids was compatible with hyperfunction of these glands Unless this is a form of compensatory (secondary) hyperfunction it would be difficult to reconcile the invariable absence of hypercalcemia during attacks with primary hyperparathyroidism although the latter could explain the fall in serum phosphorus which usually occurs [13] The adrenal and other endocrine glands are not reported to have shown gross abnormalities Whether histologic studies were routinely performed on these glands in the studies reported is not stated

The only pathologic changes which appear to be specific for periodic paralysis are found in the skeletal muscles Goldflam [8] was the first to report the occurrence of histologic changes in the muscles in two brothers with periodic paralysis The lesion comprised an increase in the diameter of the individual muscle fibers rarefaction of the primitive fibrils and the formation of numerous vacuoles within individual muscle fibers The appearance of hypertrophied fibers in the muscles of patients with periodic paralysis has been confirmed by Schmidt [46] and Crafts [66] The more striking picture of vacuoles within the muscle fibers has attracted the attention of numerous authors who have debated whether these findings were a manifestation of real pathologic change or merely artifactual Goldflam [8] himself considered that the changes bore a causal relationship to the paralytic seizures and used their presence to exclude the possibilities that the paralysis resulted from neurosis or from a lesion of the central nervous system In agreement with Goldflam [8] Singer and Goodbody [14] were convinced that the vacuolar changes were not seen in sections of normal muscle and believed that the extraordinary fissuring seen on transverse sections of skeletal muscle was the result of some essential abnormality in the muscle fibres' Schmidt [46] found that some of the vacuoles were filled with granular masses which stained like glycogen with Best's carmine stain while others were filled with a homogeneous transparent shiny substance which did not take up the stains used He was emphatic that these changes were not seen in muscle from control subjects Neel [90] apparently unwilling to accept the verdict of his pathologist that the changes were artifacts pointed out that similar findings were absent from the muscles of his patient's unaffected sister as well as from the muscle of three patients of similar age who did not have periodic paralysis Zabriskie et al [71] confirmed the findings of Schmidt [46] that some of the vacuoles were filled with glycogen granules and shared the view that these lesions were indicative of pathologic change in the muscles Biernond and Daniels

[12] and Allott and McArdle [16] also observed the vacuoles but the former authors dismissed them as artifacts

Conn et al [23 24] showed by serial biopsies on a patient with sporadic periodic paralysis that the vacuoles were easily recognizable when the patient was paralyzed by glucose and insulin on a high sodium intake (Fig 27 9A) but disappeared completely (on biopsy from the same muscle) at a time when sodium depletion and a low sodium intake had reduced the sodium content of the muscle (see Table 27 2) as shown in Fig 27 9B. Specific stains failed to demonstrate the presence of either

Fig 27 9 Photomicrographs of skeletal muscle from Patient R S showing vacuoles within fibers of muscle paralyzed on high-sodium diet (A) and disappearance of these vacuoles on low-sodium diet when paralysis could not be induced (B)

glycogen or lipid material in the vacuoles. These findings suggest that the vacuoles contained mainly sodium chloride and water and that the accumulation of excessive amounts of sodium and water within the muscle fibers might constitute an important step in the pathogenesis of periodic paralysis.

## GENETICS

From the numerous published pedigrees of patients with familial periodic paralysis it is evident that in most instances the defect is inherited as an autosomal dominant trait with complete penetrance [12 45 47 56 57 59 62 86 93 114 160 161]. From three of the larger kindreds collected from the literature and shown in Fig 27 3 it can readily be seen that one of the parents of each affected individual invariably suffered from the malady. A few authors have published pedigrees which indicate dominant autosomal inheritance with incomplete penetrance [40 44 46 60 89]. Three of these are illustrated in Fig 27 2.

It is not always clear whether the authors who described incomplete penetrance were able to verify the alleged absence of attacks in the parents of affected individuals by personal interviews with these parents.

At least in some instances evidence of incomplete penetrance is inconclusive, since it appears to be based upon the testimony of relatives whose contact with the allegedly unaffected individuals might well have been tenuous. A few patients have experienced their first attacks of paralysis in the fourth decade of life [10 12 93] or even at the age of 56 [9 61] and many authors [7 12, 47 56 90] have described members of affected families who in an entire life span experienced only a single attack or a few mild attacks all occurring within a brief period of time. It is likely, therefore as Dalinghaus [48] and Oliver et al [93] have suggested, that variability in the age of onset and in the severity and frequency of the paralytic seizures may explain why the disease appears to have skipped a generation in some families. If this suggestion is correct it might be expected that penetrance would appear to be less complete among females than among males since females are generally considered to suffer less severe and less frequent attacks than males [56 63]. That females do predominate in the apparently skipped generations [40 46 89] lends support to this hypothesis. The apparently normal parents of affected offspring might represent then *formes frustes* of the disease and might be expected to possess the fundamental underlying defect. Nobody has yet attempted to induce paralysis in such allegedly unaffected parents of sufferers from the disease by the repeated administration of glucose and insulin or of salt retaining adrenocorticoids.

One report has been published by Khan [78] describing the only Indian family in the literature in which the gene appears to have been sex linked and recessive. The eight affected individuals in three generations were all males and in each case the disorder was inherited from an unaffected female. No affected male transmitted the condition to his offspring. The females in the pedigree were summarily dismissed with the statement that all the sisters of the listed males were unaffected. Since the members of this family were Mohammedan peasants among whom the women usually refrain from social and even professional medical contact outside the family circle it is not unlikely that the author was unable to interrogate the females in person. The importance of a reliable history from the females of this family is evident when one reflects that if only one of the women had been found to have suffered from paralytic episodes the pedigree would have lost its seemingly unique features, becoming very similar to those published by Sagild [40] Brisset [97] and others, with a strong predilection for males because of incomplete penetrance in females. In the absence of more details this kindred cannot be considered to have established the existence of sex linked recessive inheritance in periodic paralysis.

Talbott [49] has implied that the existence of skipped generations in some families with periodic paralysis indicates recessive inheritance in those families. This implication is not generally considered valid as

Gates [162] has pointed out. Similarly Brisset's [97] claim to have shown recessive inheritance in periodic paralysis cannot be accepted. His claim rests entirely upon the finding of incomplete penetrance among the females in a pedigree where the occurrence of the malady in 8 of 17 adult descendants clearly indicates dominant inheritance.

There appears therefore to be no conclusive evidence in the literature which is incompatible with the view that familial periodic paralysis is inherited as an autosomal dominant trait with complete penetrance in most families and with apparently incomplete penetrance in others.

### *Sporadic Cases of Periodic Paralysis*

Patients with no family history of paralytic episodes have attacks which are identical with the hereditary type in their clinical manifestations and in their biochemical changes [21 49 163]. The age of onset is very similar (Fig. 27.1) the same stimuli provoke attacks and thyrotoxicosis may bring to light the underlying metabolic defect by precipitating attacks in both groups of patients [10 98]. While it is possible that inadequacy of information about the forebears may have been responsible for the failure to establish the truly hereditary nature of some allegedly sporadic cases, a strong case has been made for the existence of truly sporadic instances of periodic paralysis by the diligent studies of Gaupp and Kalden [163]. These authors traced and made personal contact with 186 out of the 261 living descendants of the grand parents of one of their patients and obtained adequate information from relatives and family physicians about another 50 of the descendants leaving only 17 per cent of the pedigree unaccounted for. Of the 236 individuals about whom adequate information was available none had any history at all suggestive of periodic paralysis.

Evidence for or against the existence of truly sporadic instances of periodic paralysis might be obtained by observing the responses of the siblings and parents of apparently sporadic patients to the administration of glucose and insulin or to adrenal salt retaining corticoids or simply to heavy meals followed by rest as Neel [90] suggested 30 years ago. No fall in serum potassium concentration and no paralysis resulted from the administration of 4 mg 9 $\alpha$  fluorohydrocortisone and 10 gm NaCl to the father and mother of a young man with sporadic periodic paralysis [70]. While this result will obviously need to be confirmed on the relatives of other sporadic patients, the consistency with which this stimulus will induce attacks of paralysis in affected patients supports the conclusion that the parents of this patient probably did not possess the genetic trait for periodic paralysis.

Of the 92 apparently sporadic cases of periodic paralysis which the authors have been able to trace in the literature [6 10 14 15 19 21 23-25 31 50-58 64-69 76 78 82-8, 87 88 91 92 94 98-103 105

111, 116 118, 163-170] only 7 have been females [10 19, 21, 51, 84 88, 99] The scarcity of female cases and the fact that their allegedly sporadic nature has sometimes been inconclusively documented [10, 19, 88, 99] or actually disproved by the transmission of the disorder to the offspring [21] allow the speculation that sporadic cases may not really occur at all in females It is possible that the apparently sporadic cases in males might result from inheritance of a recessive sex linked gene In the present state of ignorance however it cannot be stated with certainty whether sporadic instances of periodic paralysis result from recessive inheritance, whether they represent new mutations which will manifest dominant inheritance in succeeding generations, or whether their defect is acquired and not genetically determined in any way

## TREATMENT

The many forms of treatment that have been used in patients with periodic paralysis have included administration of Prostigmine, Meecholy, carbaminoyl choline [90] desiccated thyroid [32] ovarian substance [38] and use of an oxygen tent [116] and milk diets with the content of carbohydrate not higher than 10 per cent [137] Avoidance of high carbohydrate intake, particularly in the evening appears to be a reasonable recommendation to the patient in view of the ease with which glucose loads precipitate attacks

Potassium salts were used empirically for many years before the detection of hypokalemia during the attacks [14, 16 60] The administration of large doses (5 to 15 gm) of potassium salts (usually KCl) appears, in the opinion of most observers to shorten the duration of paralysis considerably when given during an attack [13 16 19, 21, 61, 89 95 114 116] Improvement in muscle function may occur within 15 min or may be deferred for 2 hr or more and has been attributed to a reversal of the abnormally rapid influx of potassium into the tissues [19] Of the few authors who have failed consistently to observe beneficial effects from the therapeutic administration of potassium some have probably used too small doses [15 98] and others may have been treating adynamia episodica hereditaria (which is aggravated by KCl) rather than periodic paralysis [31] Many observers have felt that the daily administration of KCl serves a useful prophylactic function [17 136] especially if KCl is administered at night [17] Others who have been enthusiastic about the effectiveness of KCl during attacks have expressed scepticism about its prophylactic efficacy and have even observed more frequent attacks when daily treatment with potassium chloride has been provided [16 21 25] Such a deleterious effect might conceivably result from stimulation of increased aldosterone output if these patients react like normal subjects to a high potassium intake [171 172]

The use of a 10 mEq sodium intake 'desalting' with diuretics (chlorothiazide, mercurials, acetazolamide), and quantitative replacement of potassium losses has been very effective in preventing both spontaneous paralysis and precipitation of attacks by the most potent of exciting stimuli including glucose and insulin and 2 $\alpha$  methyl 9 $\alpha$  fluorohydrocortisone. Conn et al [23, 24, 117] have made these observations in two severe and in two mild cases under strict supervision in a metabolic ward. One of the severely affected patients had thyrotoxicosis; after thyroidectomy he has required no sodium restriction or other treatment to avoid further seizures. The two patients who were mildly affected, experiencing attacks less than once a month, have both remained free of attacks at home over the past 6 months and 2 years respectively on a 10 mEq sodium diet (including salt free bread and cheese, no milk, and with supplementary calcium gluconate and vitamins). The patient with severe and frequent attacks of paralysis has frequently admitted his inability to adhere to the low sodium dietary regimen and has resorted to taking Randall's solution of potassium salts every day. He continues to experience many mild bouts of weakness and an attack of paralysis lasting several hours approximately once a week. It seems likely that there will be many such patients with severe forms of the disease who will fail to benefit from attempted sodium restriction because of dietary difficulties preventing strict adherence to the regimen. Under such circumstances the treatment will probably fail to reduce the sodium content of the skeletal muscle sufficiently to prevent paralysis resulting from a sudden influx of either sodium or potassium. Drugs (the steroidal spiro-lactones) are now becoming available. These inhibit the effects of circulating aldosterone and are successful in protecting patients from induced attacks of paralysis over the short periods of time that they have been used in these studies. It may be that chronic administration of these or similar agents may become a practicable form of therapy if the drugs prove to be well tolerated when administered over long periods of time.

Since in most patients there is a natural tendency for paralytic seizures to become less frequent and less severe after the age of 30 or 40 years, the mildly and moderately severely afflicted individuals may be treated satisfactorily with sodium restriction, intermittent use of oral diuretics plus potassium replacement, and perhaps aldosterone antagonists. On the other hand, periodic paralysis has proved to be lethal to 10 per cent of the sufferers [49], while many others have developed progressive muscular atrophy, often incapacitating. In families (such as that reported by Holtzapffe [60] and by Myers [61]) with a high incidence of severely afflicted patients, the untimed and as yet unrecommended use of subtotal adrenalectomy might be considered. This, however, remains in the realm of experimental medicine.

Patients who have coexisting periodic paralysis and thyrotoxicosis are

treated with complete success by elimination of the thyrotoxicosis, by appropriate use of propylthiouracil, subtotal thyroidectomy, or radioactive iodine [53, 55, 94, 98]

## SUMMARY

1 Periodic paralysis is a disease characterized by muscular paralysis without loss of consciousness speech or sensory modalities, in persons who enjoy good health and strength between attacks. Paralytic attacks commonly start between the ages of 7 and 21 years reach maximum intensity and frequency in the third decade of life and frequently tend to subside in middle or old age. The frequency of attacks varies from once in a lifetime to every night for many years. Males are more frequently and more severely involved than females.

■ Attacks of paralysis may be induced by a variety of "stresses" by factors which increase the rate of glucose utilization by rest and muscular relaxation particularly at night and by the administration of epinephrine desiccated thyroid corticotropin adrenocortical extract and mineralocorticoids.

3 Prodromata are usually absent. The flaccid paralysis with which the subjects characteristically awaken from sleep may be partial or complete but rarely involves facial and respiratory muscles. Tendon reflexes and muscular reactivity to electrical stimulation are abolished during paralysis. The frequent occurrence of cardiomegaly hypertension, bradycardia and arrhythmias and nausea vomiting constipation and reduced bowel sounds during paralysis of skeletal muscles suggests that the defect may involve the myocardium and smooth muscle as well. Severe thirst and increased fluid intake often precede attacks. Oliguria is usual during paralysis. Recovery is frequently heralded by severe diuresis and sweating.

4 Serum potassium concentration may be normal or lowered between attacks but always falls abruptly as an attack of paralysis develops. This fall is not due to external losses of potassium from the body. Urinary potassium output is reduced in parallel with and presumably because of the falling serum potassium concentration. An increased arteriovenous difference in serum potassium concentration before and during attacks has suggested that increased uptake of potassium by the tissues constitutes a cardinal feature of the paralysis. Determinations of the potassium and sodium content of biopsied skeletal muscle have confirmed a shift of potassium into the muscle without measurable change in intramuscular sodium concentration during paralysis.

5 Muscular strength is increased by potassium chloride administration but only after a delay when the arteriovenous difference in serum potassium concentration indicates that potassium is being lost from the tissues. Between attacks the potassium concentration in the muscles

is lowered and the sodium concentration is raised as in primary aldosteronism and other conditions of chronic potassium depletion. The exchangeable body potassium tends to be low and the exchangeable body sodium tends to be high. Retention of sodium and chloride usually precedes and accompanies both spontaneous and induced attacks. The high sodium content of the muscles probably predisposes them to paralysis. Since reduction of the sodium concentration, without change in the potassium concentration by 'desalting' with a low sodium diet, diuretics and potassium replacement frequently renders the muscles immune to the paralytic effects of glucose and insulin and of mineralocorticoid administration.

6 Attacks of paralysis are preceded by or associated with increased urinary excretion of aldosterone and of 17 ketosteroids and less consistently of 17 hydroxycorticoids. The increased glucocorticoid activity and 17 ketosteroid excretion are an integral part of the spontaneous paralytic attacks and do not occur in severe attacks induced by DCA and by ammonium glycyrrhizinate. Increased glucocorticoid secretion is not essential for the induction of paralysis.

7 Increase in aldosterone or aldosterone like activity is the only known factor which is common to practically all the means whereby paralysis may be induced; it therefore probably plays a significant role in the pathogenesis of paralysis. Sodium deprivation which abolishes most if not all of the physiologic effects of aldosterone affords protection from paralytic attacks.

8 The administration of glucose and insulin increases aldosterone output in normal subjects as in patients with periodic paralysis. It is probable that patients with periodic paralysis have neither adrenocortical adenomata nor any other intrinsic abnormality in their adrenal glands as the scanty autopsy evidence would confirm. Presumably periodic stimuli to adrenocortical hypersecretion of aldosterone—and other steroids—occur in patients with periodic paralysis.

9 The pathogenesis of paralytic seizures can be explained without postulating a primary defect in the muscle membrane but it is also possible that a defect in the normal partitioning of sodium or potassium between muscle and extracellular fluid might constitute the 'trigger' which stimulates periodic hypersecretion of aldosterone in this condition.

10 The defect in periodic paralysis might consist in intermittent excessive stimuli from the hypothalamus to the secretion of aldosterone and of the pituitary tropic hormones. This is suggested by the increased urinary excretion of follicle stimulating hormone reported during attacks of periodic paralysis, the similarity of the condition in thyrotoxic and euthyroid patients and the reported occurrence of periodic paralysis in patients with concomitant manifestations of hypothalamic disorders.

11 When death has occurred during a paralytic attack, it has usually

been due to respiratory causes. Autopsies and muscle biopsies have been largely unrevealing except for showing the presence of characteristic vacuoles within muscle fibers. Some of these are filled with granules which stain like glycogen; others appear to be filled with fluid.

12 In many instances periodic paralysis is clearly inherited as an autosomal dominant trait usually but not always with complete penetrance. A sporadic form almost certainly exists also. Families with periodic paralysis may have an increased incidence of migraine, epilepsy, and progressive muscular atrophy.

## Chapter 28

### Adynamia Episodica Hereditaria

---

*Jerome H. Conn and David H. P. Streeten*

The literature of the past 60 years contains a number of hints recognizable in retrospect of differences between the usual cases of classical periodic paralysis and the group recently described as adynamia episodica hereditaria [1]. Tyler et al. [2] were the first to appreciate that because the serum potassium level always fell during attacks in patients with the usual periodic paralysis, the consistent absence of hypokalemia in a family which they studied indicated the existence of at least two types of the disorder. These authors considered however that the clinical features in their patients were indistinguishable from those of periodic paralysis. This opinion was strongly supported by numerous published case reports of patients clinically identical with theirs described as having periodic paralysis. Sagild et al. [3] described a similar family and McArdle [4], referring to a family that he had studied, suggested the need for a separate name for this group of patients. Gamstorp and Mjones [1] were the first to draw attention to a number of clinical features such as the absence of changes in serum potassium level and in the electrocardiogram during attacks which prompted them to delineate from the main group of patients with periodic paralysis a group whose disorder they proposed to name adynamia episodica hereditaria.

In these patients the attacks of weakness usually started at an earlier age than in periodic paralysis, occurred more often by day than by night, were less widespread, less severe, and shorter. The attacks tended to be precipitated by hunger and by KCl administration and to be relieved by the ingestion of food. In a comprehensive review of the previous literature Gamstorp [5] found no less than 13 reports [2, 3, 6-16] of individuals or families whose clinical manifestations and normal potassium concentration during attacks strongly suggested the diagnosis of adynamia episodica hereditaria rather than that of classical periodic paralysis.

manent muscular weakness occurred in 2 of the 138 patients described by Gamstorp [5].

### *Inciting Factors*

In all these patients attacks are most likely to occur during rest after severe muscular exercise [2 5-8 11-13 20]. Attacks may be brought on at will in some individuals by complete relaxation at any time of the day. Cold and dampness tend to bring on attacks [3 19] and it has been reported that epinephrine [18], emotional stress [2] 20 to 30 units of insulin [11] and glucose (200 gm) [18] will precipitate attacks. Tyler et al [2] have pointed out that a heavy meal at night will not cause any weakness within 2 hr but will frequently precipitate an attack the next morning. All these factors which precipitate attacks in adynamia episodica hereditaria may have a similar effect in periodic paralysis. In contrast with periodic paralysis however it has been reported that hunger frequently excites attacks of weakness in adynamia episodica hereditaria [5 19] while the ingestion of glucose or of a meal during the day appears to ward off an impending attack [5]. In contrast with periodic paralysis the administration of KCl in doses of 2 to 3 gm in children and 4 gm by mouth in adults almost always precipitates attacks [3]. One wonders whether or not KCl would precipitate attacks if such patients were maintained on diets very low in sodium.

## LABORATORY FINDINGS

Serum potassium has always been normal [2 10 12 18] or elevated [5 11] during attacks of weakness or paralysis whether the attacks occurred spontaneously or were induced by KCl administration.

The urinary potassium far from showing the sharp fall seen in attacks of periodic paralysis tended to rise during the seizures of adynamia episodica hereditaria [4 5 21 22].

The electrocardiogram showed lightly increased amplitude and a peaked appearance of T waves [3 5 20] reflecting the hyperkalemia during the attacks.

Exchangeable potassium is said to have been normal in three patients [22] though the actual figures have not yet been published.

The serum phosphorus has fallen in attacks [5] as in periodic paralysis. No abnormal findings have been encountered in serum albumin, globulin or cholesterol [15], sodium chloride,  $\text{CO}_2$ , Ca and Mg [3]. Hematocrit, fasting blood sugar [1], BMR [15], electroencephalogram and cerebrospinal fluid [3] have all been normal.

Blood eosinophil count has been observed to fall by more than 50 per cent in 19 out of 20 in attacks of spontaneous attacks and in 3 out of 11 attacks precipitated by KCl [3].

Four more reports have been found [17-19] of a condition which fulfills the criteria laid down by Gamstorp [5]. A recent report [20] of a family described as having *adynamia episodica hereditaria* has been published. It is not known whether the underlying pathogenic mechanism differs significantly in these two groups of patients but in view of the differences in clinical features, *adynamia episodica hereditaria* will be considered separately here.

## CLINICAL FEATURES

### *Age of Onset*

This is usually earlier in *adynamia episodica hereditaria* than in periodic paralysis, the condition is often recognized during early infancy. Thus among 108 patients in two families described by Gamstorp [5] the attacks started in the first 5 years of life in 50 per cent and before the age of 10 years in more than 90 per cent. This onset in the first decade of life contrasts with the onset in periodic paralysis which begins usually in the second or third decades as shown in Fig. 27.1

### *Description of Attacks*

Attacks occurred more frequently by day than by night [5, 6, 8, 10, 20] and 27 of the 138 patients described by Gamstorp [5] never experienced nocturnal seizures. Attacks occurred at night too [5, 6, 18] however, and tended to be more severe than the daytime seizures [20]. The duration of weakness or paralysis was very variable, lasting occasionally for 1 or 2 days but more frequently terminating within 10 to 45 min [5, 8, 9, 12]. One individual (G. D. H.) [19] described by Buzzard [6] in 1901 as having periodic paralysis has drawn attention to two main types of attacks in himself: (1) "ordinary attacks" of slight weakness involving a few or many muscle groups lasting up to an hour occurring as often as four times a day and resulting from such unpleasant experiences as hunger, cold, diarrhea or severe exercise and (2) "continuing attacks" with beaten, exhausted feelings in the legs lasting for several days. Many authors have described the ability of these patients to "walk off" attacks [2, 6, 8, 13, 21] as can patients with periodic paralysis. Severe sweating may occur during the seizures [6, 8, 20, 21]. A positive Chvostek sign was present in 25 per cent of Gamstorp's patients between attacks [5]. This sign was elicited in both the patients described by Kaplan et al. [20] but in one of these patients precipitation of an attack by potassium chloride administration was required to bring out the sign. Tyler et al. [2] have remarked upon the muscular build of a number of these patients. This often gives the appearance of the pseudo hypertrophy seen in childhood progressive muscular dystrophy. No deaths have been reported during paralytic seizures but per

manent muscular weakness occurred in 2 of the 138 patients described by Gamstorp [5]

### *Inciting Factors*

In all these patients attacks are most likely to occur during rest after severe muscular exercise [3 5-8 11-13 20] Attacks may be brought on at will in some individuals by complete relaxation at any time of the day Cold and dampness tend to bring on attacks [5 19] and it has been reported that epinephrine [18] emotional stress [2] 20 to 30 units of insulin [11] and glucose (200 gm) [18] will precipitate attacks Tyler et al [2] have pointed out that a heavy meal at night will not cause any weakness within 2 hr but will frequently precipitate an attack the next morning All these factors which precipitate attacks in adynamia episodica hereditaria may have a similar effect in periodic paralysis In contrast with periodic paralysis however it has been reported that hunger frequently excites attacks of weakness in adynamia episodica hereditaria [5 19] while the ingestion of glucose or of a meal during the day appears to ward off an impending attack [5] In contrast with periodic paralysis the administration of KCl in doses of 2 to 3 gm in children and 4 gm by mouth in adults almost always precipitates attacks [5] One wonders whether or not KCl would precipitate attacks if such patients were maintained on diets very low in sodium

## LABORATORY FINDINGS

Serum potassium has always been normal [2 10 12 19] or elevated [5 11] during attacks of weakness or paralysis whether the attacks occurred spontaneously or were induced by KCl administration

The urinary potassium far from showing the sharp fall seen in attacks of periodic paralysis tended to rise during the seizures of adynamia episodica hereditaria [4 5 21 22]

The electrocardiogram showed slightly increased amplitude and a peaked appearance of T waves [3 5 20] reflecting the hyperkalemia during the attacks

Exchangeable potassium is said to have been normal in three patients [22] though the actual figures have not yet been published

The serum phosphorus has fallen in attacks [5] as in periodic paralysis No abnormal findings have been encountered in serum albumin globulin or cholesterol [18] sodium chloride  $\text{CO}_2$  Cr and Mg [5] Hematocrit fasting blood sugar [5] BMR [18] electroencephalogram and cerebrospinal fluid [5] have all been normal

Blood eosinophil count has been observed to fall by more than 50 per cent in 19 out of 20 instances of spontaneous attacks and in 3 out of 11 attacks precipitated by KCl [5]

Urinary creatinine output has increased significantly on the day of the attack [3 17]

The electromyogram has revealed muscle action potentials which are always significantly shortened during paresis a change opposite to that seen in periodic paralysis (see Electromyographic and Chemical Changes in Muscle Chap 27)

All the patients studied have had an increased sensitivity to intra arterial injections of acetylcholine Thus 50 to 100  $\mu$ g acetylcholine produced a motor response in 5 patients, while 100 to 300  $\mu$ g was required in normal subjects This suggests a degree of hypopolarization of the muscle end plate both during and between attacks in adynamia episodica hereditaria

### PATHOLOGY

Tyler et al [2] have drawn attention to the presence of irregular clusters of nuclei along the more slender of the muscle fibrils and to the occurrence of vacuoles in the muscle Apparently these vacuoles are identical with those observed frequently in periodic paralysis (see Mortality and Pathologic Findings, Chap 27) Some of the vacuoles [2] contained unstained debris or appeared empty others contained granules which stained like glycogen with Best's stain However determination of the muscle content of glycogen has failed to show any abnormality

### PATHOGENESIS

There is little doubt that adynamia episodica hereditaria is a clinical entity which can be differentiated with reasonable ease from periodic paralysis Its strikingly earlier age of onset milder course and lack of incapacitating or fatal sequelae provide good practical grounds for differentiating it from periodic paralysis

On the other hand some of the other clinical differences may have been overemphasized While meals are said to improve symptoms during the day one wonders how conclusively this effect has been established in individuals whose weakness is mild and usually lasts for only 10 to 45 min without any treatment Furthermore it is heavy meals at night which are particularly likely to precipitate attacks in periodic paralysis and Tyler et al [2] have found precisely the same effect of heavy meals taken at bedtime in patients with adynamia episodica hereditaria viz attacks occurring early the next morning

The absence of a fall in serum potassium would be most unusual in severe attacks of quadriplegia occurring in patients with periodic paralysis but is certainly quite common in periodic paralysis during the mild spells of weakness which occur frequently between major bouts of paralysis This has been reported by Pudenz et al [23] Bickerstaff [24]

and others and is evident from Fig 27 II Moreover there is considerable doubt that KCl has any therapeutic effect in such spells of transient weakness in patients with periodic paralysis The beneficial effects in periodic paralysis of potassium even in severe attacks are seldom seen within 15 min of administration and may be delayed for 2 hr or more [25] Furthermore some patients with a clinical picture typical of adynamia episodica hereditaria are stated to have experienced relief from potassium administration despite the absence of a fall in serum potassium during the weakness [18]

Evidence suggesting a similar pathogenesis in the two conditions includes (1) the tendency in both conditions for attacks to be precipitated by a heavy meal at night [2] by glucose [18] or insulin administration [11] and by emotional stress [2] all of which can be expected to stimulate an increased adrenocortical output of aldosterone (see Nature of the Relationship between Transient Hyperaldosteronism and Paralysis Chap 27) (2) the fall in blood eosinophil count [5] which probably signifies increased adrenocortical secretion of hydrocortisone during seizures of adynamia episodica hereditaria as has been shown to occur in attacks of periodic paralysis (see Laboratory Findings Chap 27) and (3) presence of the identical pathologic lesion comprising vacuoles within the muscle fibers in both conditions [2 6]

Conclusive evidence on exactly how the pathogenic mechanisms of adynamia episodica hereditaria and periodic paralysis differ and in what respects they may be identical can be expected to result from future studies of muscle electrolyte composition adrenocortical activity and the ability to precipitate paralysis with potent salt retaining corticoids in patients with adynamia episodica hereditaria

## GENETICS

Dominant autosomal inheritance with complete or almost complete penetrance has been reported by most writers [2 3 7 8 12 13 17] and is shown in Fig 28 1 Penetrance was incomplete in one family [18] The incidence of the disorder among males and females in hereditary cases has been equal [21] though Tyler et al [2] found that the symptoms were more severe in males than in females A history of migraine or severe headaches has been encountered among relatives unaffected by adynamia episodica hereditaria [8 9] Apparently genuine instances of sporadic occurrence of this condition have been reported [9 10]

## TREATMENT

Administration of potassium salts either has proved of no avail [2 11 15] or has actually aggravated the symptoms [3 12] This finding is not sur

prising in view of the ease with which attacks have been precipitated by KCl. Premedication with glucose has prevented the precipitation of attacks by KCl [5].

Wolf [11] has reported very good results from the use of desiccated thyroid which given to seven patients completely protected them from attacks for  $1\frac{1}{2}$  years.

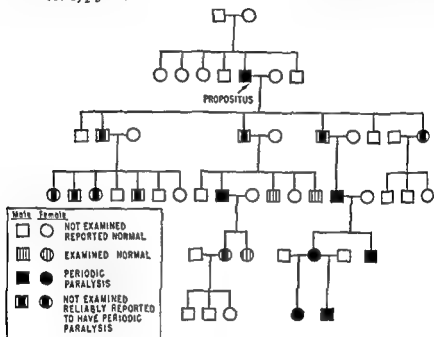

Fig 28-1 Genealogy of adynamia episodica hereditaria as exemplified by Gamstorp's family from Møller [5].

Intravenous calcium gluconate (5 to 20 ml 10 per cent solution) appears to have shortened attacks [1]. Cod liver oil (500 ml per week) is claimed to have prevented all attacks from 14 days after commencement of its administration [19].

Gamstorp et al [6] have recommended a regimen of moderate physical exertion, enough sleep at night and regular meals at short intervals during the day.

It is to be expected that newer information regarding the pathogenesis of adynamia episodica hereditaria and its probable relationship to periodic paralysis will be forthcoming and that rational therapeutic procedures will result.

## Chapter 29

### Pseudohypoparathyroidism

---

*Frederic C. Bartter*

Pseudohypoparathyroidism (PIIP) is a term introduced by Albright, Burnett, Smith, and Larson [1] to describe a syndrome in which the serum shows the abnormalities of hypoparathyroidism but which differs from 'idiopathic' or surgical hypoparathyroidism in that parathyroid extract has little or no effect in correcting the abnormalities. Whereas a typical case may present numerous distinctive features not found in idiopathic hypoparathyroidism, there is no general agreement as to the precise physical or biochemical criteria required to establish a diagnosis. Although this uncertainty has led some authors to include under pseudohypoparathyroidism cases with but a single feature and has even led a few to question the existence of the entity, an extensive and convincing body of literature now leaves little doubt that it exists as a unique syndrome and that it is a familial disease.

#### CLINICAL FEATURES

Patients with PIIP are almost invariably described as having short stature and round faces [2-3] (Fig. 29-1). They show, in addition, shortening of one or more metatarsal or metacarpal bones and shortening of the corresponding digits [4-6]. Clinical or radiologic examination may reveal areas of calcification or ossification in the skin or soft tissues. There may be exostoses typical of those seen in the syndrome of hereditary deforming chondrodysplasia [7-9]. A number of cases have been reported in siblings [2, 8-12]. If one includes in the significant family history the metatarsal and metacarpal changes resembling those of achondroplasia and the presence of exostoses, the evidence for positive family history is impressive.

The findings are not characteristic of idiopathic hypoparathyroidism. On the other hand, with the single exception of associated moniliasis [13], all the findings characteristic of idiopathic hypoparathyroidism have been reported in pseudohypoparathyroidism. These include both

tetanic and epileptic convulsions, fragility of the nails, thickness of the skull, hypoplasia of the enamel and of the roots of the teeth, cataracts and prolonged Q-T interval in the electrocardiogram. In both syndromes the serum alkaline phosphatase level is generally normal but may be elevated [2, 14, 15], the bones are generally thicker than average but may, indeed, be radiolucent [1, 3, 11, 16, 17] and there may be scattered areas of calcification in and about the region of the basal ganglia. Abnormally high serum phosphorus concentration, abnormally low serum calcium concentration and a very low urinary calcium excretion are characteristics of both.

Fig. 20-1 Face of patient G. H. with pseudohypoparathyroidism. (By permission of H. Etlrick et al. [6].)

Patients with PHIP are frequently mentally retarded [1-3] and the face is frequently expressionless, masklike, or suggestive of parkinsonism [3, 4]. In a number of reports the bones are described as showing increased trabeculation and coarse structure [11, 16, 17]. The first two features are difficult to evaluate quantitatively, and bone biopsy, which would allow better definition of the third, has been performed in only one atypical case [14].

As originally described [1] the syndrome differed in two cardinal features from idiopathic hypoparathyroidism: normal or indeed increased amounts of parathyroid tissue were demonstrated on exploration, and there was resistance to

administered parathyroid extract. The resistance can be demonstrated by two different types of test, the results of which may differ significantly.

In the first reported case [1, Patient I. S.] parathyroid tissue appeared to be normal in amount after 6 months of treatment with dihydrotachysterol. In two other cases [1, G. H. and S. M. B.] biopsy of the parathyroids showed hyperplasia. Figure 29-2 is a photomicrograph of the tissue removed from G. H. and S. M. B. The findings are in striking contrast to those reported for idiopathic hypoparathyroidism, in which parathyroid tissue has not been found despite careful search at autopsy on a number of occasions [10, 18]. MacGregor and Whithead note that in one reported case there was strong presumptive evidence for idiopathic hypoparathyroidism, but normal parathyroid tissue was found at autopsy [4]. In this patient a single normal serum calcium value was reported. The metatarsal and metacarpal bones were not described.

The literature contains a further report of a parathyroid biopsy in PHP [4]. No parathyroid tissue was found and the results were termed 'inconclusive' by the authors. Unfortunately biopsy has not been performed in any of the remaining cases thus far reported. Accordingly the diagnosis has been established on clinical grounds and with the use of

Fig. 212. Microscopic picture of parathyroid gland. A. A normal subject. B. patient G H [ ] with pseudohypoparathyroidism. C. patient S M B [•] with pseudohypoparathyroidism. Note the hyperplasia in (B) and (C). ( $\times 105$ )

parathyroid extract a procedure which as discussed below may give equivocal results.

The association of chemical hypoparathyroidism with hyperplasia of the parathyroids and resistance to parathyroid extract led Albright and associates to postulate an end-organ defect in PHP. They drew an analogy to Sebright Bantam roosters which develop the plumage of hens under androgenic stimulation.

### RESPONSE TO PARATHYROID EXTRACT

Response to parathyroid extract may be tested by observing the immediate changes in urine and serum phosphorus when the extract is

given intravenously, or by observing changes in serum calcium and phosphorus and in calcium and phosphorus balance when the extract is given intramuscularly over a period of days. The first type of test is generally done exactly as described by Ellsworth and Howard [20] thus it is possible to compare the quantitative results of one laboratory with those of another. The second type of test has been carried out under widely varying conditions of calcium and phosphorus intake and with differing doses of parathyroid extract so that quantitative evaluation of results from different laboratories is very difficult.

In the Ellsworth Howard test the patient is fasted and urine is collected for measurement of phosphorus content for 3 hr. Two hundred units of parathyroid extract are then given intravenously and urine and serum phosphorus are measured for a further period of 3 hr. In patients with idiopathic or surgical hypoparathyroidism urine phosphorus may rise to reach five to ten times control values and serum phosphorus may fall by 1.0 to 2.0 mg per 100 ml during the procedure. In normal subjects there may be an increase in urine phosphorus to two to four times control values and serum phosphorus may fall by 0.5 to 1 mg per 100 ml [1, 2]. In patients with PHP the urine phosphorus characteristically shows no change or a rise to not more than twice control values and serum phosphorus does not change.

The clinical application of this test presents four difficulties. In the first place parathyroid extract may lose its potency. To control this source of confusion the same batch of extract is often tested on a normal subject. In the second place normal subjects may show little change in urine or serum phosphorus even with potent extract [21]. This difficulty may be eliminated if it is possible to test the extract not on a normal subject but on a subject with known idiopathic hypoparathyroidism. In the third place some subjects with pseudohypoparathyroidism well documented in all other respects may show a rise of urine phosphorus to as much as five times the control values [2, 4]. This type of response may be a result of nonspecific action of the extract on the kidneys [22, 23]. It is known that commercially available extracts quite consistently increase renal plasma flow and some of them increase glomerular filtration rate and thus filtered phosphorus as well [23, 24]. This third source of confusion is eliminated if glomerular filtration rate measured during the Ellsworth Howard test shows no significant rise. Glomerular filtration rate has not generally been measured and hence many published data cannot be properly evaluated. A fourth source of confusion arises from reports of patients with steatorrhea and no other signs of PHP who show an elevated serum phosphorus level [25] instead of the lowered serum phosphorus level generally seen with steatorrhea. These patients may show no change of urine phosphorus during the Ellsworth Howard test [26]. This difficulty may be eliminated when patients with this syndrome

are tested with parathyroid extract over a period of days as discussed below

In the first report of the syndrome of PHP all three subjects were shown to be resistant to parathyroid extract given intramuscularly over 11 to 17-day periods as judged from negligible changes in serum phosphorus and calcium. Thus the confusion attendant upon nonspecific effects of the extract on renal function when administered intravenously was avoided and also the studies showed that in PHP there is resistance to the calcium raising property of parathyroid extract as well as to its ability to promote phosphate diuresis. These findings strongly imply that the effect of parathyroid hormone on bone [27] as well as on the renal tubules is diminished or absent in PHP. This conclusion derives also from the observation that most patients with PHP show normal to increased bone density; normal serum alkaline phosphatase values and no signs of osteitis fibrosa cystica such as loss of lamina dura, subperiosteal resorption or bone cysts. If parathyroid hormone is indeed secreted in excess in this syndrome, osteitis fibrosa would be expected unless the resistance involves the bones as well as the kidneys.

Resistance to parathyroid extract administered over a period of days has been used to aid in the diagnosis of PHP in only a few reported cases [1, 2, 4, 28]. In one case the initial response to parathyroid extract given intravenously was normal but the longer test confirmed the clinical impression of PHP by producing little change in serum phosphorus and only a transient change in serum calcium [2].

The effects of parathyroid extract given intravenously or intramuscularly may be influenced by previous administration. Acquired resistance to parathyroid extract has been well documented and may be associated with the presence of precipitating antibodies [29]. Accordingly resistance to extract in a previously treated patient may give a false-positive diagnosis of PHP.

The nature of the resistance to parathyroid hormone has not been clarified. Two groups of workers [2, 30] showed that the serum of patients with PHP would not interfere with the action of parathyroid extract given under standard conditions. In one study [2] dogs showed a normal rise in serum calcium with parathyroid extract given together with or previously incubated with serum from a patient with PHP.

## METASTATIC OSSIFICATION

Patients with PHP characteristically form bone in subcutaneous tissues and along fascial planes. This is true bone with normal histology. There is no evidence of osteomalacia (wide osteoid seam) and no evidence of osteitis fibrosa (osteoclasts and fibrosis). Ectopic bone formation is the cardinal sign of myostatic ossification syndrome in which

shortness of metacarpal and metatarsal bones closely resembling that found in achondroplasia is also a regular feature. This has suggested [2] that a common genetic defect may relate PHP and myositis ossificans progressiva.

### ABNORMALITIES OF BONE

Abnormalities of metacarpal and metatarsal bones form a cardinal feature of PHP. These bones are characteristically short and thick. They may show abnormal curvature as well. The first, fourth and fifth metacarpals are more frequently affected than the second and third [2]. There may or may not be early union of the epiphyses; the defect appears to be essentially a failure or limitation in linear growth at metaphyseal ends of bones exactly comparable to that seen in achondroplasia.

Exostoses have been noted in a number of cases [6-7]. These are indistinguishable from those seen in the syndrome of hereditary deforming chondrodysplasia [8] and as in that syndrome are frequently reported in the parents of patients with PHP. This finding lends support to the view that PHP represents a genetically determined defect.

### GENETIC ASPECTS

As noted above, PHP has a strong tendency to occur in more than one member of a family. This is a valuable aid to differential diagnosis since familial incidence is almost unknown in idiopathic hypoparathyroidism, even though there are many more reported cases of that disorder than of PHP. In the three siblings with idiopathic hypoparathyroidism reported by Sutphin and associates [13] there was associated moniliasis in all cases and all subjects also suffered from 'familial Mediterranean target oval cell syndrome'. In the family reported by Goldman and associates [52] hypocalcemia was found in three brothers who showed none of the other stigmata of PHP. The one patient who was studied showed a transient response to parathyroid extract given intravenously when a single hourly urine phosphorus reached four times the control value. In the family reported by Lachman [10] (Patients 57 to 59) the three siblings who were thought to have idiopathic hypoparathyroidism were short, mentally sluggish and childish and all had one or more short metacarpal bones. They were not tested for responsiveness to parathyroid extract but it seems probable that they suffered from PHP. If PHP is a genetically determined disorder and if it involves more than a single gene [2] one would expect to find incomplete cases. Although it is possible that the patients referred to above with steatorrhea, elevation of serum phosphorus level and resistance to parathyroid extract [20, 26] represent the abnormality in parathyroid function alone, this hypothesis cannot be tested directly until the nature of the resistance in PHP is more fully understood.

## PSEUDO PSEUDOHYPOPARATHYROIDISM

One type of incomplete PHP has been well documented. It is of interest that a number of reports have appeared describing cases with all the characteristic abnormalities of PHP except those associated with hypoparathyroidism [33-37]. They have been given the name of pseudopseudohypoparathyroidism. The abnormalities in these patients include the short metacarpal and metatarsal bones with brachydactyly, metastatic ossification, shortness of stature with roundness of the face, mental deficiency and indeed lenticular opacities despite absence of hypocalcemia or of any history thereof. These patients have normal serum calcium and phosphorus values and normal response to parathyroid extract. They do not show the calcification of the basal ganglia characteristic of idiopathic hypoparathyroidism and of PHP. This suggests that this manifestation is a result of the chemical abnormalities and is not under separate genetic determination. As in PHP, familial incidence has been reported in pseudopseudohypoparathyroidism. The presence of this incomplete syndrome lends strong support to the hypothesis that the fundamental disorder in PHP represents a genetically determined defect.

Recently Van der Werff ten Bosch [38] has reported that four of six female patients with this syndrome had gonadal dysgenesis. The nuclear pattern of three of them was chromatin negative for genetic sex.

## SUMMARY

1 Pseudohypoparathyroidism is a familial heritable disease in which the clinical and biochemical abnormalities of hypoparathyroidism are associated with skeletal abnormalities and metastatic ossification.

2 Patients are characteristically short with round faces, may have mental deficiency and show changes characteristic of achondroplasia in one or more metatarsal or metacarpal bones. True ectopic bone is found in skin and in fascial planes and there may be calcification of the basal ganglia.

3 The chemical abnormalities include hypocalcemia and hyperphosphatemia. Parathyroid extract produces little or no immediate phosphate diuresis and is ineffective in restoring serum calcium and phosphorus towards normal values. Parathyroid tissue is normal or hyperplastic. The disorder represents not a deficiency of parathyroid hormone but resistance to its effects.

4 Although only a single case has shown all the essential features (characteristic build, metacarpal defect, metastatic ossification, hypoparathyroidism, resistance to parathyroid extract in short term and long term courses and hyperplasia of parathyroid tissue) the syndrome seems to be a distinct clinical entity.

■ The syndrome of pseudo-pseudohypoparathyroidism appears to represent the same entity except that hypoparathyroidism and resistance to parathyroid hormone are absent

### Diseases of Porphyrin Metabolism

---

## Chapter 30

### The Porphyrins \*

---

*Rudi Schmid*

Since the end of the nineteenth century porphyria has aroused the curiosity and interest of clinicians and investigators alike and has received wide spread attention in spite of its relatively infrequent occurrence. A continuing interest in disorders of porphyrin metabolism is largely due to two factors: (1) the unusual variety of clinical manifestations associated with these disturbances and (2) the relative ease with which very small amounts of porphyrins can be identified and estimated owing to their unique spectroscopic and fluorescent properties.

Porphyria has been the subject of innumerable clinical reports and of many biochemical investigations but only relatively recently has information accumulated regarding the nature and location of the metabolic defects which may account for the appearance of the disease. In the last 12 years with the advent of tracer techniques impressive progress has been made and much of the biosynthetic pathway by which porphyrins and heme are formed has been clarified. This better understanding of the normal pathways of metabolism provides an indispensable basis for the elucidation of the biochemical defects involved in the various types of porphyria.

The first authentic case of porphyria described in the literature was reported by Baumstark in 1874 [1] under the diagnosis of pemphigus leprosus. A craftsman with cutaneous photosensitivity and obvious liver disease was found to excrete a urinary pigment which was designated as uroburohaematin and which had unmistakably the spectroscopic and solubility properties of the compound now known as uroporphyrin. A few years later MacMunn [2] reported on five patients suffering from 'subacute rheumatism' or idiopathic pericarditis whose urine contained a red pigment which he named urohaematin.

This work was supported in part by grant A 1833(C) from the Public Health Service.

of clinical subforms with different manifestations such as abdominal colic peripheral neuropathy and pruritus psychosis and coma. In addition patients who excreted abnormal amounts and types of porphyrins including porphobilinogen but in whom clinical manifestations of porphyria were lacking were classified as having *latent porphyria* [14 16 18 19]. Such persons many of whom were blood relatives of patients with manifest porphyria were believed to exhibit the inherited metabolic abnormality but for unknown reasons they remained free of symptoms. It was recognized however that in such asymptomatic patients acute clinical manifestations could at times be precipitated by ingestion of relatively small amounts of sedatives such as barbiturates and sulfonal [14 20-22]. In these instances the drug undoubtedly converted a pre-existing latent porphyria into an acute form [14].

On the other hand acute porphyria was reported with increasing frequency in individuals who were addicted to sedatives but in whom no evidence of preexisting porphyria or familial occurrence of the disease could be elucidated [18 21 23 26].

Soon after 1888 the year of the introduction of sulfonal and related compounds into clinical medicine [20] massive haematoporphyrinuria was observed in two patients with chronic sulfonal poisoning [26]. By 1900 Taylor [27] was able to collect from the literature 34 cases of fatal sulfonal poisoning most of these patients showed a marked increase in haematoporphyrin excretion in the urine. Particularly striking was a patient with fatal porphyria described by Duesberg [24] who over a period of many years had ingested very large amounts of Sedormid (allyl isopropyl acetyl carbamide) and other sedatives. His urine exhibited high concentrations of uroporphyrin and at autopsy intense porphyrin fluorescence was demonstrable in the liver gallbladder and bile ducts [28].

The concept that in previously normal individuals sedatives of the sulfonal group could produce a porphyria like syndrome gained strong support from animal experiments. In rabbits it was observed that sulfonal poisoning regularly produced marked haematoporphyrinuria [6 20 29-31]. With more refined analytic methods Fischer and Duesberg [32] demonstrated uroporphyrin in the urine of such rabbits but a few years later Waldenstrom and Wendt [33] failed to confirm these observations. The question remained undecided until 1952 when it was discovered that in rabbits the sedative Sedormid also produced a syndrome which exhibited many biochemical similarities to human hepatic porphyria [34]. On a weight basis these animals were found to excrete more porphobilinogen and porphyrins than porphyric patients in relapse. Nevertheless certain biochemical differences between the hereditary human disorders and experimental Sedormid porphyria in animals were recognized. In the latter condition there was a precipitous fall in liver catalase activity

Although "urohaematin" undoubtedly was a porphyrin it is questionable whether MacMunn was actually describing uroporphyrin. Its solubility in chloroform and its spectroscopic properties which differed slightly from Baumstark's "urorubrohaematin" [3] suggest that MacMunn may have been dealing with the pigment which is today designated as coproporphyrin. In spite of the recognized slight spectroscopic differences Salkowski [3], Hammersten [4], Garrod [5], Stokes [6], Sallet [7], Anderson [8], Nebelthau [9] and others regarded these pigments for practical purposes as identical with hematoporphyrin<sup>1</sup> which Hoppe-Seyler [10] and Nencki and Sieber [11] had prepared from hemoglobin by the action of concentrated sulfuric acid. Garrod [5] discovered "haematoporphyrin or allied pigments" in the urine of 76 out of a group of 196 patients of a mixed hospital population. His conclusion that "haematoporphyrin" was an "almost constant constituent of urine in health and disease" reached far ahead into modern concepts of porphyrin metabolism. During the next two decades massive "haematoporphyrinuria" was observed in a large number of patients exhibiting such diversified clinical manifestations as photodermatitis, colicky abdominal pain, bizarre involvement of the nervous system or psychic disturbances.

### PROPOSED CLASSIFICATIONS

Guenther [12] was the first in attempting to arrange the reported cases according to certain recurrent symptom patterns. His classification distinguished between *haematoporphyrin congenita* and *haematoporphyrin acuta*, the latter including idiopathic and toxic forms. In addition he designated a few cases as *haematoporphyrin chronica*, a group which he originally considered as a separate entity but later tended to regard as mild and late forms of *porphyrin congenita* [13]. In such patients the photosensitivity and the excretion of red urine are indeed characteristic of what is now termed congenital (erythropoietic) porphyrin, yet these two conditions differ strikingly in their clinical course and particularly in the time of onset of the first symptoms. In 1937 Waldenström [14] proposed to substitute the term *porphyrin cutanea tarda* for Guenther's original "chronic porphyrin". In recent years the fundamental difference between *congenital photosensitive porphyrin* as a defect in the erythropoietic system and *porphyrin cutanea tarda* as a disturbance in liver metabolism has become well recognized [15-17].

Under the term *acute porphyrin* Waldenström [14] included a variety

<sup>1</sup> Hematoporphyrin is not found in nature but can be prepared from hemoglobin *in vitro*. In the earlier literature hematoporphyrin was used as a generic term to designate all naturally occurring porphyrins as well as those which can be derived from hemoglobin *in vitro*. Hematoporphyrin, hematoporphyrinuria and porphyrin were terms employed interchangeably.

From the above discussion it is evident that it may at times be difficult if not impossible to decide whether a patient is suffering from an inherited disorder or from an acquired disturbance of porphyrin metabolism. This is more frequently the case in porphyric patients exhibiting photosensitivity in whom liver disease is a prominent feature but similar difficulties may be encountered in patients with acute symptoms who have used excessive amounts of sedatives. The problem is further complicated by the fact that increased excretion of porphobilinogen and of uroporphyrins has been observed in patients with hepatic neoplastic and neurologic diseases in whom symptomatic manifestations of porphyria were absent [44-45].

The following discussion will be limited to those forms of porphyria for which a hereditary basis has clearly been established. For a more general consideration of disturbances in porphyrin metabolism the reader is referred to recent reviews by Watson [39], Rimington [46], Waldenström [10], Vannotti [47] and Bénéard [48].

## RELATIONSHIP OF PORPHYRINS TO HEMOGLOBIN METABOLISM

The name *porphyrin* appeared for the first time in the literature in 1871 when Hoppe Seyler [10] prepared haematoporphyrin from hemoglobin. A few years later Nencki and Sieber [11] identified haematoporphyrin as a derivative of hemin, the prosthetic group of hemoglobin. Although a number of investigators [2, 3, 6, 7, 31] recognized the slight spectroscopic differences between hematoporphyrin and the porphyrins excreted in the urine for practical purposes these pigments were considered as identical. This led to the widely accepted but erroneous belief that the urinary porphyrins are derived from breakdown of hemoglobin [2, 6, 19, 47, 49-51] although several observers including East and Weiss [31], Garrod [5] and later Liebig [52] raised doubts as to the validity of this concept. It was not until 1920 that direct proof became available for the independence of porphyrin excretion from hemoglobin breakdown. Fischer and his coworkers [53] found significant structural differences between hematoporphyrin and the porphyrins present in the urine. More important still was the finding that the urinary porphyrins belong in part to an isomeric series different from that of hemoglobin protoporphyrin (Fig. 30-1).<sup>a</sup> These and other observations led Fischer to sug-

The classification of porphyrin isomers is based on the four synthetically prepared isomers of etioporphyrin designated as I, II, III, and IV. In nature only porphyrins belonging to isomer series I and III are found. The etioporphyrin of hemoglobin and of other heme proteins has the basic structure of a porphyrin of type III isomer. However, since the  $\beta$  positions of the pyrrole rings are substituted by three different radicals, the total number of possible isomers for protoporphyrin is 15. The protoporphyrin occurring in all known heme proteins is designated as isomer 9a and corresponds to the basic structure of etioporphyrin in III.

[32] the urinary porphyrins were almost exclusively of the type III isomer [34] and the concentrations of proto- and coproporphyrin in the liver and bile were greatly increased [36]. On the other hand, no increase in the urinary excretion of  $\delta$ -aminolevulinic acid was observed [37] although porphobilinogen was present in high concentrations [36].

These animal experiments support the concept that in persons who habitually ingest large amounts of sedatives, a toxic form of porphyria may develop. This is distinct from latent hereditary porphyria in which relatively small amounts of sedatives may precipitate an acute attack. Since detailed studies of human toxic porphyria have not been reported it is not known how this condition differs from the hereditary forms of porphyria. The chemical findings in experimental Sedormid porphyria suggest that the metabolic derangement in toxic porphyria may be quite different from that in the genetically controlled disorders.

The concept that some forms of human porphyria may not have a hereditary basis has recently gained additional support from studies of patients with cutaneous porphyria. The term "porphyria cutanea tarda symptomatica" has been proposed by Waldenstrom [16] to describe patients in whom outspoken liver disease is associated with photosensitivity and marked elevation of porphyrin excretion. In this group he included some of the patients who previously had been reported as having porphyria cutanea tarda by Brunsting [33], Watson [39], Bolgert et al [40], Schmid et al [41] and Barnes [42] and in whom liver disease was a prominent feature. Waldenstrom believes that in such patients the liver disease usually of alcoholic or nutritional origin is the primary disorder and that the disturbance in porphyrin metabolism is merely a secondary manifestation [16]. An interesting case of seemingly acquired cutaneous porphyria was recently reported by Tio Tiong Hoo [43]. In an 80-year-old woman photosensitivity and marked porphyrinuria had gradually developed over the course of a year, when she was discovered to have a large benign liver cell adenoma. On resection this was found to contain large amounts of proto-, copro- and uroporphyrin; the surrounding liver tissue was normal. Following the operation the cutaneous manifestations disappeared and the porphyrin excretion returned to normal values. This seemed to indicate that the defect in porphyrin metabolism was limited to the hepatic tumor.

Although in most of the above-discussed patients there is no positive family history nor evidence suggesting a preexisting latent porphyria the possibility cannot be excluded with certainty that a predisposition to porphyria may have been inherited and the acquired liver disease may merely have served to bring out the clinical and chemical manifestations of this disturbance. Moreover it should be noted that several genetically distinct forms of porphyria exhibiting cutaneous manifestations have been described in which the hereditary nature of the disorder has clearly been established. These will be discussed later.

zymes such as cytochromes catalase and peroxidase [60]. Although the amounts of these heme proteins in the organism may be quite small as compared with hemoglobin, some of them may have a more rapid turnover than hemoglobin. For liver catalase, for example, the half life has been estimated to be only a few days [30, 61], a rate of turnover which requires the daily synthesis of a considerable amount of protoporphyrin. It is therefore conceivable that metabolic abnormalities resulting in excessive formation and liberation of porphyrins and of porphyrin precursors may occur in any tissue of the body, but that the liver is of particular importance as the site of such disturbances. In fact, with the exception of congenital erythropoietic porphyria, the liver seems to be the major site of the metabolic derangement in most forms of human porphyria and in experimental porphyria produced by Sedormid. This has led to the proposal to classify these disturbances under the group name of *hepatic porphyria* [18, 39, 41].

## BIOSYNTHESIS OF PORPHYRINS AND OF HEME

Little was known prior to 1946 about the chemical building blocks from which the body synthesizes porphyrins and heme. In that year Shemin and Rittenberg [62, 63] observed that after feeding isotopically labeled glycine to man or animals, the concentration of the label in the circulating heme of hemoglobin rose rapidly, remained more or less

Fig. 30-2. Concentration of  $N^{15}$  in hemoglobin heme of a normal subject given 10 gm glycine- $N^{15}$  (31.65 atom per cent excess  $N^{15}$ ) during the first 4 days of the experiment (By permission of C. H. Gray [30]).

steady for about 100 days and then rapidly declined (Fig. 30-2). The disappearance of the label from the circulating heme was accompanied by a marked though temporary increase in the fecal excretion of labeled urobilinogen [64, 65] (Figs. 30-2, 30-14). These observations permitted the conclusions that (1) glycine is a specific precursor of heme protopor-

gest that in congenital (erythropoietic) porphyria porphyrins of the type I isomer are synthesized along with and parallel to hemoglobin formation in developing erythroid cells of the bone marrow. Isser considered this "atavism" as a partial regression into a phylogenetically and ontogenetically more primitive phase of development. As will be seen later, this concept is to a large extent in agreement with more recent studies.

Fig. 30-1 : Coproporphyrin of type I and type III isomer series. In porphyrins of type III isomer, the sequence of the side chains in the  $\beta$ -positions of pyrrole ring D is reversed. Me = methyl.

Although as a result of these observations it was generally accepted that porphyrins may be formed along with hemoglobin in the bone marrow, it soon became apparent that this hypothesis was not applicable to patients with acute porphyria and porphyria cutanea tarda. On the basis of extensive clinical and necropsy studies, Waldenström [64] came to the conclusion that there must exist a fundamental difference in the pathogenesis of the various forms of porphyria. He reasoned that "the porphyrin must either be an anomalous product on the way to hemoglobin which is then excreted (or) the other possibility is to try to find another source from which porphyrin might appear." The nature of this other source was suggested by autopsy studies [28, 35, 41, 47, 65-69] and by analysis of biopsy material obtained from patients with porphyria [41]. These investigations were supplemented by animal experiments as discussed in the preceding section.

As a result of these observations it became increasingly clear that not only the erythropoietic system but also other organs and particularly the liver may be important sites of porphyrin formation. This is not surprising since most mammalian cells can synthesize the porphyrins which are required for the formation of essential heme-containing en-

[70-76] With methyl labeled acetate for example highest labeling of heme protoporphyrin is observed in the carbon atoms 6 and 9 (Fig. 30-4). The activity is present in positions 4, 8, and 3 [76]. Moreover there is equal labeling each to each in the position pairs 6 and 9, 4 and 5, and 3 [76]. The labeling pattern obtained in protoporphyrin synthesized from succinate 1-4  $C^{14}$  is pictured in Fig. 30-4 [79].

Fig. 30-4 The labeling pattern obtained in protoporphyrin synthesized from succinate 1-4  $C^{14}$ . Carbon 1, which gives rise to the CO is the carbon of the original carboxyl group attached to carbon 6 (By permission of D. Shemin [10]).

These findings indicate that the biosynthesis of the protoporphyrin molecule requires 8 moles of glycine and 8 moles of a four-carbon intermediate of the tricarboxylic acid cycle most likely succinate [70-74]. The possible ways by which succinate and glycine could combine to form a pyrrole unit are limited by the finding that the  $\alpha$ -carbon atom of glycine is always equally utilized for both the pyrrole ring carbon atoms and the methene bridge carbon atoms [70-77].

The above and other observations led Shemin and his coworkers [70-78] to suggest that the intermediate which is formed by condensation of glycine and succinate is the five carbon aminoketone  $\delta$ -aminolevulinic acid (ALA) (Fig. 30-3). With the use of ALA 5  $C^{14}$  in a system of hemolyzed duck red cells the position of this aminoketone as a true intermediate in porphyrin biosynthesis has been well documented [79-81]. Not only was the labeling pattern of the  $\delta$  carbon atom of ALA identical with that of the  $\alpha$ -carbon atom of glycine [70-79] (Fig. 30-3) but the heme synthesized from an equimolar amount of ALA 5  $C^{14}$  was about sixty five times more radioactive than heme synthesized from glycine

phyrin, (2) hemoglobin of the circulating erythrocytes remains outside the general metabolic pool of protein interchange (3) the majority of normal red cells have a mean life span of about 120 days (4) a large fraction of the fecal urobilinogen is derived from the breakdown of circulating red blood cells, and (5) the metabolites of heme protoporphyrin are not reutilized for the synthesis of hemoglobin in newly formed erythrocytes

Additional studies carried out in various laboratories showed that blood from ducks and chickens which contains nucleated erythrocytes [66

Fig 30-3 The carbon atoms of protoporphyrin derived from the  $\alpha$ -carbon of glycine and the  $\delta$ -carbon of  $\delta$  aminolevulinic acid (ALA) (By permission of D. Shemin [6])

67] and blood from rabbits which had been made anemic to produce a high percentage of reticulocytes [69] is able to synthesize labeled heme from glycine  $\text{C}^{14}$  in vitro. The availability of these systems greatly facilitated subsequent studies which revealed that all four nitrogen atoms [62-69, 70] and eight carbon atoms of the protoporphyrin molecule are derived from glycine [70-72] (Fig 30-3). Four of the carbon atoms are still attached to the nitrogen atoms of glycine while four are not forming the methene bridges which link the four pyrrole rings to form the porphyrin ring (Fig 30-3). All eight carbon atoms are derived from the  $\alpha$  carbon atom of glycine while the carboxyl carbon of glycine is not utilized for any of the carbon atoms of porphyrin [72, 73].

The remaining 26 carbon atoms of protoporphyrin arise from intermediates of the tricarboxylic acid cycle [70, 74]. Acetate labeled either in the methyl or in the carboxyl group = ketoglutarate-5  $\text{C}^{14}$  or  $\alpha$  keto glutarate-1  $\text{C}^{14}$  or citrate 1, 5  $\text{C}^{14}$  lead to characteristic and predictable labeling patterns which strongly suggest that the same four-carbon chain is utilized in the formation of both sides of all four pyrrole rings

reactions all involving the transformation of glycine [70]. The formation of porphyrins is only one of these various metabolic pathways

### BIOSYNTHESIS OF $\delta$ AMINOLEVULINIC ACID (ALA)

The elucidation of the exact mechanism by which ALA is formed by condensation of glycine with active succinate was a difficult task. Shemin's observations indicated that the system required some particulate matter present in nucleated red cells of birds or in reticulocytes of mammals [70-78-79] but absent from mature mammalian erythrocytes [88]. The findings have now been confirmed and extended [83-86] but the nature

Fig 30-6 Condensation of succinyl CoA with glycine in the presence of pyridoxal phosphate (Adapted from Hikiuchi et al [87])

of the cellular particles has not been conclusively established [80] (Fig 30-6). In more recent studies Hikiuchi et al [87], Gibson [88] and Sawyer and Smith [89] have observed enzymatic synthesis of ALA from succinyl CoA in particle-free extracts obtained from *Rhodospseudomonas spheroides* or *Rhodospirillum rubrum*. A forty to eighty fold purification of the soluble enzyme has been achieved [87].

Shemin and Wittenberg's original suggestion that the 'active' four carbon intermediate may be succinyl CoA [74-76-77] has gained strong though indirect support from studies of heme and porphyrin formation in pantothenate deficient ducks [90] and in *Tetrahymena vorax* [91]. The more recent studies by Gibson, Laver and Neuberger [84], Shemin et al [87], Granick [85] and Brown [92] have provided conclusive evidence that succinyl CoA is indeed the intermediate which condenses with glycine. The succinyl CoA can be derived from  $\alpha$ -ketoglutarate by the action of  $\alpha$ -ketoglutarate dehydrogenase [83-84] or it may be formed from succinate in the presence of ATP [84-87-92] (Fig 30-6).

first by Westall [102]. The soluble enzyme ALA dehydrase has been purified from a number of sources including duck erythrocytes [98], chicken erythrocytes [103] or liver [99-100] and spinach leaves [104]. Reduced glutathione is required for activation of the enzyme system [99-100-105]. SH group inhibitors such as iodoacetamide and *p*-chloro mercuribenzoate have an inhibitory effect [100]. The latter can be overcome by the addition of reduced glutathione [99-100]. In addition marked inhibition of ALA dehydrase has been noted with the chelating agent ethylenediaminetetraacetic acid a finding which suggests that a metal may be essential in this enzymatic step. This has recently been

Fig 30-7 Condensation of 2 moles of  $\delta$  aminolevulinic acid to form 1 mole of precursor pyrrole (porphobilinogen). The carbon atoms bearing the labels are the original  $\alpha$ -carbon atoms of glycine (By permission of Dr Shemin [6]).

confirmed by the observation that ALA dehydrase contains copper [106]. Furthermore ducklings deficient in copper were found to exhibit reduced ALA dehydrase activity in liver and erythrocytes [106]. Similar observations have been reported in copper-deficient chicks [107] and copper deficiency has been shown to lead to hypochromic anemia.

Two moles of ALA are required for formation of 1 mole of PBG [70-98] (Fig 30-7). Heme synthesized from labeled ALA has twice the specific activity of that which is formed from an equimolar amount of PBG with the same radioactivity [70-98]. These findings confirmed the earlier reports by Falk, Drechsel and Rimington [108] and by Bogorad and Granick [109] that PBC is a specific precursor and an obligatory intermediate in the biosynthesis of porphyrin and of heme.

#### BIOSYNTHESIS OF UROPORPHYRINOGEN

In considering the conversion of PBC to porphyrins and to heme two important findings have to be taken into account. In earlier studies it had been assumed that simple linear condensation of four pyrrole units would lead to formation of the next metabolic intermediate uroporphyrin; the latter would then undergo stepwise decarboxylation to yield protoporphyrin. It soon was discovered however that this simple scheme was not correct. In a variety of systems which were able to convert PBC to

The condensation of glycine with succinyl CoA requires the presence of pyridoxal phosphate. The requirement for pyridoxal was demonstrated along three different lines of evidence. In blood of pyridoxine-deficient ducklings Schulman and Richert [90] observed reduced heme synthesis from glycine C<sup>14</sup>, a defect that could be corrected by the addition of pyridoxal phosphate. This finding is in line with earlier observations by Wintrobe [93] that pigs deficient in vitamin B<sub>6</sub> produced small pale red cells with a low content of hemoglobin and of free protoporphyrin. In vitro compounds known to inhibit enzymes which contain pyridoxal phosphate [94] have been shown to reduce the formation of ALA [83, 84, 87] and of porphyrins [89, 95]. Marked inhibition was obtained with L-penicillamine, nicotinic acid hydrazide, cyanide, L-cysteine and p-chloromercuribenzoate. Finally, biosynthesis of ALA [83, 84, 87, 97] and of porphyrin [89, 90, 91] was found to be enhanced by the addition of pyridoxal phosphate in vitro. These findings indicate that pyridoxal phosphate is essential for the condensation of glycine with succinyl CoA and it appears likely that the cofactor is firmly bound to the condensing enzyme (Fig. 30-6) [83, 84, 87].

The primary condensation product is probably  $\alpha$ -amino  $\beta$ -ketoadipic acid [70, 78, 80] (Fig. 30-5, 30-6) but the ease with which this compound undergoes spontaneous decarboxylation has prevented its isolation [84]. However, the finding that in the intact rat injection of the diethyl ester of this aminoketone resulted in urinary excretion of porphobilinogen provides at least indirect evidence to support this hypothesis [160].

The biosynthetic pathway of ALA formation is summarized in Fig. 30-6. Aerobic reactions which are inhibited by dinitrophenol [85, 96] convert  $\alpha$ -ketoglutarate [83, 84] or succinate [87, 92] to succinyl CoA. An enzyme which requires pyridoxal phosphate as a cofactor catalyzes the condensation of succinyl CoA with glycine to form  $\alpha$ -amino  $\beta$ -ketoadipic acid. By decarboxylation the latter is converted to ALA. The initial reaction of this pathway requires a functioning tricarboxylic acid cycle and thus is oxygen dependent; the condensing enzyme system is operative under anaerobic conditions. In mature mammalian erythrocytes the absence of a functioning tricarboxylic acid cycle obviously precludes formation of succinyl CoA and hence of ALA.

#### BIOSYNTHESIS OF PORPHOBILINOGEN (PBG)

With the establishment of ALA as an obligatory intermediate in porphyrin and heme biosynthesis, studies of the subsequent enzymatic steps were greatly facilitated. ALA dehydrase was found to catalyze condensation of 2 moles of ALA to form a precursor pyrrole [97-100] (Fig. 30-7). The theoretical formulation of the structure of this pyrrole [78] yielded the same structure as porphobilinogen (PBG) [101], a chromogen excreted in the urine of patients with acute porphyria [14] and isolated

type III isomer is as yet incomplete sufficient information is available to formulate a reasonable working hypothesis [113] (Fig 30-9) Incubation of PBG with an enzyme system obtained from *Chlorella* [109] or from red cell hemolysates [124-125] results in formation of porphyrins of type III isomer However if such a system is heated for 15 min at 55 C it is changed in such a way that only porphyrins of type I isomer are formed This finding suggests that the enzyme porphobilinogenase may have more than one component Indeed Bogorad [116-117] and Hoare and Heath [114] succeeded in preparing two separate enzyme fractions PBG deaminase and uroporphyrinogen isomerase It appears that one of the actions of PBG deaminase is to remove the amino group and to condense individual monopyrroles to form polypyrrylmethanes (Fig 30-9) [105-117] The enzyme is relatively heat stable and if acting alone converts PBG to uroporphyrinogen I [116] Inhibition has been observed with silver and mercury ions and with formaldehyde [116] The latter may be of biologic importance as a possible regulatory mechanism promoting formation of uroporphyrinogen III since formaldehyde is formed in the deamination of the aminomethyl group of PBG [126]

If uroporphyrinogen isomerase from wheat germ is added to a system containing PBG and PBG deaminase the reaction product is uroporphyrinogen III [117] (Fig 30-9) Since by itself uroporphyrinogen isomerase reacts with neither PBG nor uroporphyrinogen I [113-117] it is clear that its enzymatic function is dependent on some effect of PBG deaminase on PBG It seems reasonable to assume that the isomerase acts by combining PBG with a noncyclized intermediate which is produced by the action of PBG deaminase on PBG [117] Such an intermediate may be a di- or tripyrrylmethane [105-117] (Fig 30-9)

#### METABOLISM OF UROPORPHYRINOGEN

The further metabolism of uroporphyrinogen can proceed along two separate lines it may undergo either a stepwise oxidation to uroporphyrin or a stepwise enzymatic decarboxylation to porphyrinogens which exhibit less than eight carboxyl groups [112-114 118-124] (Fig 30-10) The oxidative process leads to uroporphyrin which is a side product and does not serve as a substrate for the enzyme uroporphyrinogen decarboxylase Nonenzymatic oxidation of uroporphyrinogen can occur by photocatalytic autoxidation a process activated by the product uroporphyrin (Fig 30-10) [105] Photooxidation is partially inhibited by glutathione ■ mercaptoethylamine cysteine or sodium ulfite and is markedly reduced under strictly anaerobic conditions or by exclusion of light [105-116] On the other hand ferric ion at acid pH catalyzes the photooxidative process [105]

The conversion of uroporphyrinogen to uroporphyrin proceeds stepwise with formation of cyclized tetrapyrroles which exhibit an oxidation

heme or to porphyrins with less than eight carboxyl groups, uroporphyrin was ineffective as a substrate and could not replace PBG [70 110 111]. The observations suggested that the true intermediate formed from PBG is not uroporphyrin but its reduced form uroporphyrinogen. Indeed Neve and his coworkers [112] found that in a hemolyzed red cell system incorporation of  $^{59}\text{Fe}$  into heme was markedly stimulated by the addition of uroporphyrinogen but not by uroporphyrin. Additional studies [104 113-118] have clearly indicated that the biosynthetic pathway from PBG to heme proceeds over a series of porphyrinogens which are colorless reduced porphyrins containing six additional hydrogen

**Fig 30-8 Metabolism of porphobilinogen.** Only porphyrinogens of type III isomer are intermediates in the biosynthesis of heme. Porphyrins of type III isomer and porphyrinogens and porphyrins of type I isomer are side products not utilized for heme synthesis. PBG porphobilinogen, UROgen uroporphyrinogen, COPROgen coproporphyrinogen, PROTOgen protoporphyrinogen, URO uroporphyrin, COPRO coproporphyrin, PROTO protoporphyrin.

atoms [119]. The oxidized porphyrins instead of being true intermediates are merely by products resulting from irreversible oxidation of the corresponding porphyrinogens (Fig 30-8) [120].

A second point of importance is that the protoporphyrin of hemoglobin and of other heme containing proteins belongs to the type III isomer series (protoporphyrin 9a) [53] (Fig 30-1). Heme proteins containing a porphyrin of type I isomer have never been found in nature [121]. Thus, any biosynthetic scheme proposed for the formation of heme must include a mechanism which permits synthesis of type III isomer porphyrins. Since in nature isomerization of porphyrins by ring opening and reclosure in a different position does not appear to occur [113] the isomer type formed must be determined at the time of the original ring closure (Fig 30-1). The exact mechanism by which this occurs is still in doubt. Several suggestions have been advanced [70 105 109 122] but they will not be discussed in detail. It may suffice to state that PBG can condense to uroporphyrin by nonenzymatic means and that under such conditions mixtures of uroporphyrin isomers are obtained [122 123].

Although knowledge regarding the precise mechanism and nature of some of the intermediates involved in the formation of porphyrins of

level intermediate between uroporphyrinogen and uroporphyrin [118 114 116] Mauzerall and Granick have suggested that these intermediates may be porphomethene and porphodimethene both of which show strong absorption at 500 mμ [118] The former has two and the latter four hydrogen atoms less than uroporphyrinogen (Fig 30-10) These partially oxidized intermediates may be obtained by slow oxidation of uroporphyrinogen with iodine in the dark or by reduction of uroporphyrin with sodium amalgam [118 119] Enzymatic oxidation of uroporphyrinogen catalyzed by a heat labile oxidase obtained from spinach leaves [116] appears to proceed along similar lines The oxidase can be separated from PBG deaminase by starch block electrophoresis and is markedly inhibited by hydroxylamine [116] Its specificity is not known and it appears to be of little biologic significance The same holds true for non enzymatic oxidation of uroporphyrinogen Since the amount of uroporphyrin normally excreted in the urine is exceedingly small as compared with the magnitude of heme synthesis the fraction of uroporphyrinogen that is oxidized and escapes from the biosynthetic path must be in

degree of specificity ALA PBG and uroporphyrin cannot replace uroporphyrinogen as substrates [113 118] Mercury copper manganese and oxygen strongly inhibit the reaction [113 118] the latter probably by enhancing autooxidation of the substrate to uroporphyrin On the other hand reduced glutathione and cysteine greatly increase the yield of coproporphyrinogen A heat stable ultrafiltrable cofactor has been described in *R. spheroides* [114] which appears to be essential for the enzymatic decarboxylation of uroporphyrinogen The isomer specificity of uroporphyrinogen decarboxylase is not known Both uroporphyrinogen I and III can serve as substrates [113 118] but the rate of decarboxylation appears to be higher for the type III isomer [113]

The removal of the four acetic acid side chains of uroporphyrinogen probably occurs stepwise and randomly so that intermediate porphyrinogens with seven six and five carboxyl groups are formed [104 113 120] Since the decarboxylating enzyme(s) appears to have a low Michaelis constant and a high turnover number [113] the concentration of the intermediate porphyrinogens at any one given time is very low and the reaction is rapidly carried through to coproporphyrinogen As for uroporphyrinogen photocatalytic autooxidation of porphyrinogens with less than eight carboxyl groups is probably of little biologic importance since exclusion of light and the presence of antioxidants in the cells maintain them in a reduced state Under aerobic conditions in vitro however porphyrins with seven to five carboxyl groups are readily obtained [103 104 113] It is not known whether the successive removal of carboxyl groups of uroporphyrinogen to form ultimately coproporphyrinogen is catalyzed by a single or by several closely related enzyme systems [113] For convenience the term uroporphyrinogen decarboxylase is used although the enzyme as defined can react with porphyrinogens which exhibit fewer carboxyl groups than uroporphyrinogen

With uroporphyrinogen I as substrate coproporphyrinogen I or its oxidation product coproporphyrin I is the end product since further decarboxylation of the type I isomer series does not occur [113 118 120 128] Protoporphyrin or heme corresponding to type I isomer has never been demonstrated in nature [121 128] With uroporphyrinogen III on the other hand enzymatic decarboxylation may yield porphyrins of type III isomer with less than four carboxyl groups [118 129] Granick and Mauzerall [129] have presented evidence which strongly suggests that an enzyme bound to insoluble components of chicken erythrocytes or of *Fuglena* is involved in the oxidative decarboxylation of coproporphyrinogen III to form the dicarboxylic protoporphyrinogen III The latter through intermediate stages of autooxidation may be converted to protoporphyrin III (9a) [104 129] The requirement for a particulate enzyme system for oxidative decarboxylation of coproporphyrinogen III has also been demonstrated by the findings of Rimington and Booy

Fig 30-10 Stepwise conversion of uroporphyrinogen to coproporphyrinogen by uroporphyrinogen decarboxylase with formation of intermediate porphyrinogens with 7  $\blacksquare$  and  $\blacksquare$  carboxyl groups. Each porphyrinogen can undergo stepwise oxidation to its respective porphomethene, porphodimethene, and finally porphyrin. (For abbreviations see Fig 30-8.)

significant. It appears likely that the exclusion of light and the presence in the cells of antioxidants such as glutathione and cysteine are of importance in keeping most of the tetrapyrroles in a reduced state [113].

The major fraction of the uroporphyrinogen is enzymatically decarboxylated to porphyrinogens with less than eight carboxyl groups [103, 113, 114, 118, 124] (Fig 30-10). Uroporphyrinogen decarboxylase activity has been demonstrated in erythrocytes of man [124, 125], ducks [112], and chickens [127], in rabbit reticulocytes [113], in *Chlorella* [109], and in *Rhodospseudomonas spheroides* [114]. With enzyme preparations obtained from rabbit reticulocytes [113] or *Chlorella* [118], anaerobic incubation of uroporphyrinogen resulted in formation of coproporphyrinogen exhibiting four carboxyl groups. The enzyme has a high

of succinyl CoA pyridoxal phosphate for the condensation of succinyl CoA with glycine and copper as part of ALA dehydratase. It appears likely that other cofactors may also be required but their nature has not yet been recognized [114].

4 ALA and PBG are obligatory intermediates in the biosynthesis of porphyrins and of heme.

5 Porphyrinogens and porphyrins of the type I isomer series are by products of heme synthesis without known physiologic function. In vivo the biosynthetic pathway is conditioned in such a way that formation of porphyrins of type I isomer is insignificant as compared with the amount of heme formed.

6 With the probable exception of protoporphyrin III (9a) porphyrins of the type III isomer series are not intermediates in heme biosynthesis but are by products resulting from irreversible oxidation of the respective porphyrinogens. The true intermediates are porphyrinogens of the type III isomer which are reduced porphyrins containing an additional six hydrogen atoms. Conversion of porphyrinogens to porphyrins occurs by photocatalytic autoxidation or by the enzyme porphyrinogen oxidase. In vivo oxidation of porphyrinogens to porphyrins is minimized by the exclusion of light and by the presence of antioxidants.

7 The dynamics of the uroporphyrinogen decarboxylase system favor the formation of porphyrins with eight carboxyl groups (uroporphyrin) and with four carboxyl groups (coproporphyrin) but smaller amounts of porphyrins with seven, six, five and three carboxyl groups are also formed.

## METABOLISM OF PORPHYRINS AND PORPHYRIN PRECURSORS IN THE INTACT ORGANISM

The bone marrow of an adult individual forms approximately 300 mg heme per day. This amount is needed for hemoglobin formation to compensate for the physiologic decay of aged erythrocytes [130]. Additional heme is synthesized for the formation of other heme proteins but the lack of precise information regarding the rate of turnover of these compounds precludes exact estimation of the total daily heme production. Undoubtedly it is considerably larger than the 300 mg required for hemoglobin synthesis in the bone marrow since heme containing compounds which are believed to be synthesized *in loco* are present in almost all aerobic cells [60]. Relative to this rate of heme formation the excretion of porphyrins and of porphyrin precursors in urine and bile is very small. If one visualizes the excreted compounds as the sum of all porphyrins and porphyrin precursors which escape during heme formation it becomes obvious that heme biosynthesis is proceeding with a remarkable degree of efficiency. It is not known how much individual organs contribute to the

[130] that with ALA or PBG as substrates addition of mitochondria to a system consisting of hemolyzed human erythrocytes greatly enhances the formation of protoporphyrin III (9a). Conversion of coproporphyrinogen III to protoporphyrin III (9a) not only involves decarboxylation of the two propionic acid side chains but it requires formation of two vinyl groups. It is therefore not surprising that *in vitro* biosynthesis of protoporphyrin III (9a) from ALA [131] PBG [108] uroporphyrinogen III [118] or coproporphyrinogen III [120] requires either aerobic conditions or the presence of some electron acceptor.

Protoporphyrin III (9a) is used for the formation of heme. It is not known whether iron is inserted at an intermediate stage of autooxidation of coproporphyrinogen or into protoporphyrin itself. The latter seems more likely since it is well known that ferrous iron readily coordinates with porphyrins but not with porphyrinogens [113-132]. *In vitro* heme may be formed nonenzymatically by simple incubation of protoporphyrin with ferrous iron at 37°C under nitrogen [132]. On the other hand Krueger et al. [133] and Goldberg [134] have presented evidence which suggests that *in vivo* incorporation of iron may be catalyzed by an enzyme system present in nucleated erythrocytes.

#### RECAPITULATION

The nearly complete elucidation of the pathways by which glycine and succinate are used for the biosynthesis of porphyrins and of heme provides an impressive example of the biochemical progress made during the last decade. There can be little doubt that the few remaining regions of uncertainty and of ignorance will soon be explored and clarified. This applies particularly to the enzymatic mechanism which catalyzes the condensation of 4 moles of PBG to form the asymmetric uroporphyrinogen III and also to the steps involved in the oxidative decarboxylation of coproporphyrinogen III to protoporphyrin III (9a).

Some aspects of the biosynthetic pathway which in the intact organism are believed to be of particular importance with regard to porphyrin metabolism are summarized below.

1 While most of the individual biosynthetic steps proceed in the absence of oxygen two reactions require aerobic conditions: (a) the formation of succinyl coenzyme A which is dependent on a functioning tricarboxylic acid cycle; (b) the oxidative decarboxylation of coproporphyrinogen III to protoporphyrin III (9a).

2 These two reactions are catalyzed by enzyme systems which are bound to cell particles and which appear to be absent in mature non-nucleated erythrocytes. On the other hand the steps from succinyl CoA to coproporphyrinogen III are catalyzed by soluble enzymes present both in nucleated cells and in mature mammalian erythrocytes.

3 The following cofactors are essential: pantothenate for the formation

## PORPHYRINS

Normal human urine contains small amounts of porphyrins. The predominant one is coproporphyrin which is excreted at a daily rate of 100 to 300  $\mu\text{g}$  [148] the values being somewhat smaller in the female [149]. Both types I and III isomers are present but the ratio is subject to considerable variation [151-152]. In a variety of conditions such as hemolytic anemia, liver disease, and lead poisoning a slight to moderate increase in urinary coproporphyrin excretion is observed [148] and significant changes in isomer ratio have been reported [18]. Coproporphyrin is also present in the bile where the daily excretion rate is estimated at 400 to 1000  $\mu\text{g}$  [148]. Thus elevated values for urinary coproporphyrin excretion may result not only from increased porphyrin production but also from liver damage leading to diversion of excretion from the biliary to the urinary route [18]. For example, Hoffbauer and his coworkers [153] have found that in rats injected coproporphyrin III is entirely eliminated by the bile unless the bile ducts are occluded or the liver damaged by carbon tetrachloride.

Other porphyrins present in normal human urine include uroporphyrin [148-154] and traces of porphyrins with seven, six, five, and three carboxyl groups [151-155-156]. Most of the uroporphyrin appears to be of type I isomer with only trace amounts of uroporphyrin III [154-157].

Protoporphyrin is normally absent from the urine [18-148] but is present in bile and feces [18-158]. Even in Sedormid poisoning where very large amounts of protoporphyrin are excreted via the bile this porphyrin could not be demonstrated in the urine [34]. As a general rule it can be said that ALA, 1-BG, and uroporphyrin are mainly excreted in the urine while coproporphyrin is preferentially and protoporphyrin exclusively eliminated via the bile.

A large fraction of the porphyrins present in normal urine is excreted in the form of *precursors* which are converted to porphyrins by exposure to light and air or more efficiently by oxidation with dilute iodine [159-161]. These precursors include probably porphyrinogens 1-BG, and possibly ALA, all of which can be converted nonenzymatically to porphyrins [100-144-162]. It appears likely that the quantity and isomer type of porphyrins formed from precursors in the urine depends to some extent on external factors such as pH of the urine and type of oxidizing agent employed [122].

Except for circulating erythrocytes, information regarding the concentration of free porphyrins in human tissues is scant. Erythrocytes contain approximately 1 to 60  $\mu\text{g}$  protoporphyrin and 1 to 2  $\mu\text{g}$  coproporphyrin per 100 ml of cells [149-163]. These values may be greatly increased in iron deficiency, hemolytic anemia, lead poisoning, and other disorders of erythropoiesis [19-39-148-164].

'pool' of porphyrins and porphyrin precursors that are excreted but it appears likely that the bone marrow and the liver are major contributors

### $\delta$ AMINOLEVULINIC ACID AND PORHOBINOCEN

In man approximately 2 mg ALA is excreted in the urine per day [19 37 136 137]. No data are available for its excretion in bile but it is believed to be negligible [32 133]. Significant elevation of ALA excretion in the urine is observed in lead poisoning [139]. On the other hand Sedormid poisoning in rabbits does not appear to result in increased ALA excretion [37] although the concentration of PBG in the urine is high [36].

Injection or oral administration of labeled ALA to man and to animals results in the excretion of a large portion of the unaltered compound in the urine [32 138 140 141]. Smaller fractions are converted to PBG, to protoporphyrin and to stercobilin the former being excreted in the urine the latter two in the bile [32, 138 140]. All three compounds are believed to be formed outside the hematopoietic system, possibly in the liver [133, 140]. In addition ALA- $14\text{C}^{14}$  gives rise to labeled  $\text{CO}_2$  in the breath [32]. A small fraction of the injected ALA is used for heme biosynthesis in immature red blood cells [70 82 138 140] but in contrast to the observations *in vitro* incorporation of ALA into heme of circulating erythrocytes is several times less than that found with equivalent amounts of labeled glycine [32 138 140]. This may in part be explained by the rapid renal excretion of the injected ALA either in unchanged form or after its conversion to PBG. In addition penetration of ALA into immature red blood cells may be a rate-limiting factor [32 139 140].

In healthy individuals daily excretion of PBG in the urine is approximately 1.0 to 1.5 mg [19 37 136 137]. At the low concentrations which exist in normal urine the conventional test for detection [142] is inadequate and gives negative results [143]. Increased urinary excretion of PBG at times is observed in patients with hepatic malignant or infectious diseases [144] and is frequently present in lead poisoning [139 147]. In animals poisoned with Sedormid [36] or related compounds [37 145] large amounts of PBG are excreted in the urine and are present in the liver but not in the bone marrow or circulating erythrocytes [36].

If injected parenterally PBG is rapidly excreted in the urine [146], fecal excretion or conversion of PBC to porphyrins is insignificant [141, 146]. In animals injected PBG cannot be demonstrated in the liver [146] suggesting that it may not pass the liver cell membrane. Similar findings have been reported for fowl erythrocytes *in vitro* [96]. It is evident however that the impermeability of the cell membrane is only relative since in instances where endogenous PBG production is increased it does escape from the cells and gain access to the urine. Thus in acute porphyria of man and in Sedormid porphyria of animals large amounts of PBG are derived from the liver and excreted in the urine [36 41 146].

## PORPHYRINS

Normal human urine contains small amounts of porphyrins. The predominant one is coproporphyrin which is excreted at a daily rate of 100 to 300  $\mu\text{g}$  [148] the values being somewhat smaller in the female [149]. Both types I and III isomers are present but the ratio is subject to considerable variation [151-153]. In a variety of conditions such as hemolytic anemia, liver disease and lead poisoning a slight to moderate increase in urinary coproporphyrin excretion is observed [148] and significant changes in isomer ratio have been reported [18]. Coproporphyrin is also present in the bile where the daily excretion rate is estimated at 400 to 1000  $\mu\text{g}$  [148]. Thus elevated values for urinary coproporphyrin excretion may result not only from increased porphyrin production but also from liver damage leading to diversion of excretion from the biliary to the urinary route [18]. For example Hoffbauer and his coworkers [153] have found that in rats injected coproporphyrin III is entirely eliminated by the bile unless the bile ducts are occluded or the liver damaged by carbon tetrachloride.

Other porphyrins present in normal human urine include uroporphyrin [148-154] and traces of porphyrins with seven, six, five and three carboxyl groups [151-156-159]. Most of the uroporphyrin appears to be of type I isomer with only trace amounts of uroporphyrin III [154-157].

Protoporphyrin is normally absent from the urine [18-148] but is present in bile and feces [18-158]. Even in Sedormid poisoning where very large amounts of protoporphyrin are excreted via the bile this porphyrin could not be demonstrated in the urine [34]. As a general rule it can be said that ALA, PBG and uroporphyrin are mainly excreted in the urine while coproporphyrin is preferentially and protoporphyrin exclusively eliminated via the bile.

A large fraction of the porphyrins present in normal urine is excreted in the form of *precursors* which are converted to porphyrins by exposure to light and air or more efficiently by oxidation with dilute iodine [159-161]. These precursors include probably porphyrinogen, PBG and possibly ALA all of which can be converted nonenzymatically to porphyrins [100-144-162]. It appears likely that the quantity and isomer type of porphyrins formed from precursors in the urine depends to some extent on external factors such as pH of the urine and type of oxidizing agent employed [122].

Except for circulating erythrocytes information regarding the concentration of free porphyrins in human tissues is scant. Erythrocytes contain approximately 15 to 60  $\mu\text{g}$  protoporphyrin and 1 to 2  $\mu\text{g}$  coproporphyrin per 100 ml of cells [148-163]. These values may be greatly increased in iron deficiency, hemolytic anemia, lead poisoning and other disorders of erythropoiesis [18-39-148-164].

## PHARMACOLOGIC ACTION OF PORPHYRINS AND OF PORPHYRIN PRECURSORS

### PHOTOSENSITIVITY

The photosensitizing activity of porphyrins is well known and has been the subject of many studies [22 165-169]. This property is probably related to the intense fluorescence of porphyrins [22] since both are produced most effectively by long wave ultraviolet radiation of about 400 mμ wavelength corresponding to the peak absorption of porphyrins in the ultraviolet region of the spectrum [22 170-172]. Uroporphyrin is believed to exhibit the strongest sensitizing effect followed by coproporphyrin, protoporphyrin has few if any photosensitizing properties [22 167 172 173]. In the famous self-experiment of Meyer Betz [168] 200 mg hematoporphyrin was injected intravenously this resulted in marked erythema and edema of the exposed parts of the body. Similar observations have recently been reported by Schwartz [174]. The photodynamic effect in the skin may be mediated by release of histamine [175].

In spite of the recognized relation between porphyrins and photosensitivity [168] the pathogenesis of *hydra aestivale* the vesicular eruption occurring on exposed parts of patients who suffer from photosensitive porphyria is not fully understood. Blum and his coworker [170] failed to produce the characteristic vesicles by exposing areas of skin of a patient with erythropoietic porphyria to ultraviolet light although the wavelength of the emitted light corresponded to the absorption maximum of porphyrins. Similar negative results were reported by Watson and by Gray [22 176]. It appears likely that only continued and chronic exposure to sunlight results in formation of vesicles. This is in line with the observation made in some of the patients with photosensitive porphyria that *hydra aestivale* may not become manifest until midsummer but that the vesicular lesions then persist well into the fall [177].

Administration of ALA to human brings results in marked but transient hypersensitivity to sunlight [82 140]. In rats injection of ALA followed by exposure to radiation from a carbon arc lamp produces marked photosensitivity [178]. Injection of PBG has no such effect. This difference is believed to be related in part to the rate at which these compounds can enter epidermal cells [178]. Fluorescence microscopic examination of skin obtained from animals injected with ALA suggests that ultraviolet radiation may enhance the intracellular conversion of ALA to uroporphyrin [173]. This is reminiscent of the photocatalytic autooxidation of porphyrinogens to porphyrins *in vitro* a process which is sensitized by the product porphyrin [105]. *In vivo* de Mello [179 180] observed that in rabbits poisoned with lead acetate or injected with the photosensitizing dye rose bengal ultraviolet irradiation results in a

marked increase in urinary coproporphyrin excretion. In analogy with the observations *in vitro* it is tempting to attribute this extra excretion of pigment to photocatalytic conversion of precursors to porphyrins [181]. It is not clear, however, why the majority of patients with acute porphyria are free from photo-sensitivity, although large amounts of porphyrin precursors are present in the liver [41] and are excreted in the urine.

The above findings may be summarized as follows. Increased concentration of preformed porphyrins in the body undoubtedly predisposes to cutaneous photosensitivity. Light of near ultraviolet wavelength is particularly effective. Vesicular eruptions of the skin are produced only after prolonged and chronic exposure to sunlight. Under experimental conditions irradiation with ultraviolet light appears to promote conversion of porphyrin precursors to porphyrins, resulting in photo-sensitivity and increased porphyrin excretion in the urine. These observations suggest that photo-sensitivity is a *relative* phenomenon and may depend on such factors as light source, length and intensity of exposure, types of porphyrins and of precursors present, and their relative concentration in the skin and in the extracellular fluid.

#### OTHER PHARMACOLOGIC EFFECTS

In addition to their photosensitizing properties, porphyrins are said to produce a variety of toxic effects, including vascular and intestinal spasm and neuropathologic changes [47, 182, 183]. Reinvestigations of the pharmacologic action of naturally occurring porphyrins, however, have failed to produce convincing evidence which would suggest demonstrable effects of these compounds on smooth muscles or on the nervous system [178, 184-186]. Further, neither injection of hematoporphyrin [168] nor excessive production of endogenous uroporphyrin, as in congenital erythropoietic porphyria, gives rise to intestinal or neurologic symptoms. Nor are such symptoms produced by injection of PBG or ALA in man or in animals [82, 140, 178, 184, 185, 187]. *In vitro* these compounds were found to be without effect on smooth muscle of rat intestine [178, 184].

In view of the negative findings, it appears doubtful whether the intestinal, vascular, and neurologic manifestations of acute porphyria can be ascribed to direct toxic effects of porphyrins or of porphyrin precursors [121, 178, 181].

#### CONGENITAL ERYTHROPOIETIC (PHOTOSENSITIVE) PORPHYRIA

##### INCIDENCE AND CLINICAL MANIFESTATIONS

Erythropoietic porphyria is a rare congenital disease occurring much less frequently than other forms of porphyria. The prominence of photo-

sensitivity and of massive porphyrinuria has often caused it to be confused with the hepatic types of cutaneous porphyria [13], although the pathogenesis of the latter disorders is fundamentally different [41]. In the earlier literature [13, 188] many of the reported cases clearly had features of the hepatic forms while in other instances the data were insufficient to permit distinction [15]. A reexamination of the cases of so-called congenital photosensitive porphyria reported up to 1964 permitted the diagnosis of erythropoietic porphyria beyond reasonable doubt in a total of 34 cases [15]. An additional 7 cases have since come to the author's attention. The 41 cases and some of their essential features are summarized in Table 30-1. Twenty-four of the patients were female and 17 male. In the earlier literature it was generally held that congenital porphyria was more common in males but this was undoubtedly caused by confusion with porphyria cutanea tarda which is more frequent in males [35-40]. As seen in Table 30-1 the disease has a wide racial distribution and has been observed in children of Japanese, Bantu, and Sudanese extraction [190, 199, 202, 219, 220, 236].

The first sign suggesting the presence of erythropoietic porphyria is usually the excretion of red urine containing much uroporphyrin but no PBG. This may be noted at birth or only during the first years of life. Although porphyrinuria is probably present at all times, the amounts of porphyrins excreted and hence the red color of the urine may show considerable daily or seasonal fluctuation [8, 41, 203]. In some instances the color of the urine was light except during periods of active photodermatitis occurring during the summer months [8, 41, 203]. In others large and relatively constant amounts of uroporphyrin were excreted over long periods of time [19].

Photosensitivity is frequently absent in the neonatal period but it may become apparent during the first years of life as exposure to sunlight increases. A vesicular or bullous eruption appears on the face, the back of the hands, and other exposed parts of the body. This is commonly referred to as *hydra aestivale*, the adjective indicating the seasonal recurrence of the lesions. The vesicles contain a serous fluid which may exhibit red fluorescence, heal slowly, and leave depressed pigmented scars. Infected bullae often ulcerate, causing marked scarring and deformity involving particularly the tips of the fingers, the ears, nose, and eyelids. After years of repeated attacks, severe mutilation may ensue with contractions of the face and loss of parts of digits and ears [13]. In other cases the cutaneous manifestations may be relatively mild, resulting in little if any scarring. In several patients a definite decrease in photosensitivity and a reduction in urinary porphyrin excretion followed splenectomy [41, 203, 207]. In one of these children [203] removal of the spleen resulted in virtual loss of photosensitivity, but porphyrin-containing vesicles were observed on those parts of the hands which became infested with scabies [177].

Hypertrichosis is a frequent finding in these patients [13 22] Fine blond downy hair resembling lanugo may cover the face and extremities [13 22 190 204 214] Deciduous and permanent teeth may show a red or brownish discoloration (erythrodontia) [13 202] but in some cases this has been rather inconspicuous [18] Under ultraviolet light however the teeth always exhibit marked red fluorescence Deposition of porphyrin in the developing teeth and in bones is believed to be due to its physical affinity for calcium phosphate [18] The presence of porphyrin in the deciduous teeth may indicate that the metabolic disorder was already present during fetal life [191]

Splenomegaly is an almost constant feature of the disease (Table 30 1) It may be absent in the neonatal period and be detected only as the patient grows older [15] In one patient the spleen was enlarged in early childhood but could no longer be palpated 10 years later [192] In three patients splenomegaly was absent this was correlated with normal erythrocyte survival and lack of hemolytic anemia [217 225] Hypertension and abdominal or neurologic symptoms so frequently observed in other forms of porphyria are not found in erythropoietic porphyria

### HEMATOLOGIC FINDINGS

In the majority of the reported cases increased hemolytic activity was present as indicated by the following findings normochromic anemia associated with elevated reticulocyte levels and circulating normoblasts normoblastic hyperplasia of the bone marrow increased excretion of fecal urobilinogen [16] Rarely the anemia was severe leading to early death [195] or requiring multiple transfusions [227] but in most patients the reduction in hemoglobin concentration was only slight and the hemolysis was largely compensated by increased red cell production It was stated that the famous case Petry [202] at the time of his death suffered from pernicious anemia in addition to congenital porphyria but Aldrich et al [203] raised justified doubt as to the correctness of this interpretation of the autopsy findings and suggested that Petry may have had an unrecognized hemolytic anemia with splenomegaly [15] In another patient originally reported by Ashby [196] and later by Carrod [197] outspoken hemolytic anemia was repeatedly demonstrated [197] At the time of her death at age 27 she was found to have a coarse-nodular cirrhosis of the liver and the bone marrow showed extensive myeloid hyperplasia and no significant erythroid haemopoiesis [197] The available information is inadequate to permit speculation as to the possible factors which could have led to this marrow failure [19]

Direct estimation of erythrocyte life span has been performed in seven patients [210 212 214 217 228 229 230] five of whom had hematologic findings suggestive of hemolytic anemia A decreased survival of autologous erythrocytes was demonstrated by the glycine- $^{51}\text{Cr}$  method in the two patients studied by Grinstein et al [228] and Watson et al [212]

by Canivet et al [217] exhibited marked hemolytic anemia [215-216]. Furthermore between the two Sudanese siblings studied by Townsend, Coles and Barnes [220] one had marked hemolytic anemia while in the other hemoglobin concentration, erythrocyte count and reticulocyte count were normal although the bone marrow showed normoblastic hyperplasia.

The mechanism responsible for the hemolytic process is not understood. The absence of a positive Coombs test and the finding of decreased survival of porphyric cells in a normal recipient [214] may be suggestive of an intracorpuseular defect. On the other hand Hausmann's observation [232] that hematoporphyrin sensitizes normal red cells to hemolysis by light *in vitro* gave rise to the speculation that the presence of porphyrins in the circulating plasma may exert a hemolytic effect *in vivo* [229]. An alternative explanation is suggested by the observations made in the fluorescence microscope that only a fraction of the normoblasts and of the immature erythrocytes contains increased amounts of porphyrins [15]. If the presence of porphyrins predisposes erythrocytes to hemolysis it is conceivable that porphyrin-laden cells may have a shortened life span whereas cells which lack excessive amounts of porphyrin may survive normally. The presence of very high porphyrin concentrations in porphyric spleens [41-214] is compatible with this hypothesis. It is possible that the life span of porphyrin-containing cells may be further shortened by exposure of the patients to sunlight. It should be noted however that none of these explanations is based on concrete experimental evidence.

Studies of unstained bone marrow preparations in the fluorescence microscope show intense porphyrin fluorescence in nucleated red cells and to a lesser degree in reticulocytes [15-41-212] (Fig. 30-11). In normoblasts most of the porphyrin appears to be present either inside or at the surface of the cell nucleus (Fig. 30-11) [15]. A fraction of the normoblasts in all developmental stages and some of the reticulocytes in the peripheral blood fail to exhibit any red fluorescence [15]. There appears to be a clear separation between fluorescing and nonfluorescing cells. Furthermore fluorescing normoblasts exhibit a morphological abnormality in nuclear structure consisting of single or at times multiple nuclear inclusions (Fig. 30-12) which stain dark with benzidine (Fig. 30-13) and which show strong absorption in the 400 m $\mu$  band [15]. This nuclear abnormality is not present in normoblasts which lack porphyrin fluorescence. It is interesting to note that similar findings have been reported in congenital porphyria of cattle [212]. These observations suggest the possibility that two different lines of erythropoietic cells may be present and that only one exhibits the defect in porphyrin metabolism [15].

In patients in whom increased hemolysis was demonstrable the excre-

In the former patient splenectomy resulted in remarkable improvement in hemoglobin concentration porphyrin excretion, and photosensitivity [203] in the latter patient, the time which has elapsed since the operation is too short to permit adequate evaluation. In the case reported by London et al [210] the average life span of the erythrocytes appeared to be normal but the reticulocyte count was elevated and the marrow showed erythroid hyperplasia. In a study reported by Roenthal et al [214] erythrocytes of a patient with erythropoietic porphyria were infused into a recipient with ulcerative colitis, and the disappearance of the donor cells from the recipient's circulation was followed by differential agglutination. Although the analysis of the results was complicated by the fact that the recipient was bleeding the findings suggested a more rapid rate of removal of the porphyrin cells as compared to cells from a normal donor. Splenectomy in this patient resulted in only temporary improvement although 4 years postoperatively survival of chromated erythrocytes was almost normal [231]. On the other hand in two siblings studied by Carnet et al [217] red cell survival as estimated by the  $\text{Cr}^{51}$  method appeared to be normal and there was no evidence of hemolytic anemia as judged by normal hemoglobin concentration reticulocyte counts fecal urobilinogen excretion and absence of splenomegaly and of erythroid hyperplasia of the bone marrow.

These seemingly contradictory results may find a possible explanation in the observation that a hemolytic component may be present during one phase of the disease but absent at other times. Thus in a patient in whom over the course of 25 years hemolytic anemia had repeatedly been demonstrated [191-192] Cray et al [229-230] found that approximately half the erythrocytes appeared to have a mean life span of less than 20 days while other red cell fractions survived for periods of 40 to 70 days and for 110 to 120 days respectively. At the time of this study the patient was believed to have a hemolytic crisis as suggested by the presence of anemia reticulocytosis normoblasts in the peripheral blood and increased excretion of fecal urobilinogen. At a later date when the reticulocyte count had returned to normal a second study of erythrocyte survival suggested that at least 80 per cent of the cells appeared to have a normal life span while only a minor fraction appeared to be removed between the thirtieth and the eightieth day. All these values were calculated on the basis of data obtained by following the  $\text{N}^{15}$  content of circulating hemoglobin heme after administration of  $\text{N}^{15}$  labeled glycine (Fig. 30-2) [229-230]. The limitations of this method for determining the apparent life span of circulating erythrocytes must be kept in mind.

The above findings suggest that increased hemolysis though present in most of the cases may be intermittent in nature and at times may be so slight as to be difficult to detect. It is interesting that the porphyrin brother of the two patients with normal erythrocyte survival reported

by Canivet et al [217] exhibited marked hemolytic anemia [215-216]. Furthermore, between the two Sudanese siblings studied by Townsend, Coles and Barnes [220], one had marked hemolytic anemia while in the other hemoglobin concentration, erythrocyte count, and reticulocyte count were normal, although the bone marrow showed normoblastic hyperplasia.

The mechanism responsible for the hemolytic process is not understood. The absence of a positive Coombs test and the finding of decreased survival of porphyrin cells in a normal recipient [214] may be suggestive of an intracorporeal defect. On the other hand, Hausmann's observation [232] that hematoporphyrin sensitizes normal red cells to hemolysis by light *in vitro* gave rise to the speculation that the presence of porphyrins in the circulating plasma may exert a hemolytic effect *in vivo* [229]. An alternative explanation is suggested by the observations made in the fluorescence microscope that only a fraction of the normoblasts and of the immature erythrocytes contains increased amounts of porphyrins [16]. If the presence of porphyrins predisposes erythrocytes to hemolysis, it is conceivable that porphyrin-laden cells may have a shortened life span, whereas cells which lack excessive amounts of porphyrin may survive normally. The presence of very high porphyrin concentrations in porphyrin spleens [41-214] is compatible with this hypothesis. It is possible that the life span of porphyrin-containing cells may be further shortened by exposure of the patients to sunlight. It should be noted, however, that none of these explanations is based on concrete experimental evidence.

Studies of unstained bone marrow preparations in the fluorescence microscope show intense porphyrin fluorescence in nucleated red cells and to a lesser degree in reticulocytes [1, 41-212] (Fig. 30-11). In normoblasts, most of the porphyrin appears to be present either inside or at the surface of the cell nucleus (Fig. 30-11) [16]. A fraction of the normoblasts in all developmental stages and some of the reticulocytes in the peripheral blood fail to exhibit any red fluorescence [16]. There appears to be a clear separation between fluorescing and nonfluorescing cells. Furthermore, fluorescing normoblasts exhibit a morphological abnormality in nuclear structure consisting of single or at times multiple nuclear inclusions (Fig. 30-12) which stain dark with benzidine (Fig. 30-13) and which show strong absorption in the 400 mμ band [15]. This nuclear abnormality is not present in normoblasts which lack porphyrin fluorescence. It is interesting to note that similar findings have been reported in congenital porphyria of cattle [212]. These observations suggest the possibility that two different lines of erythropoietic cells may be present and that only one exhibits the defect in porphyrin metabolism [16].

In patients in whom increased hemolysis was demonstrable, the excre-

Fig 30-11 Unstained bone marrow smear of a patient with erythropoietic porphyria photographed in the fluorescence microscope ( $\times 800$ ). Red fluorescence (reproduced in white) is particularly intense in the normoblastic nuclei. The polychromatophilic erythrocyte in the left lower corner exhibits a lesser degree of porphyrin fluorescence. (By permission of J. Schmid et al. [41])

Fig 30-12 Bone marrow smear from a patient with erythropoietic porphyria stained with Wright's stain. The nucleus of the large normoblast shows a central inclusion. (By permission of J. Schmid et al. *Acta haematol* 10:153, 1953.)

Fig 30-13 Bone marrow smear from a patient with erythropoietic porphyria stained with benzidine. Abnormal normoblasts contain dark-staining nuclear inclusions. Nuclei of normal immature normoblasts appear granular (left border); those of normal mature normoblasts white (left lower corner). Hemoglobin-containing erythrocytes stain dark (By permission of R. Schmid et al [16]).

tion of fecal urobilinogen was elevated [15 41 203 214 229]. More important was the observation that a major fraction of the excreted bile pigments was not derived from breakdown of hemoglobin of mature circulating erythrocytes [65 210 228 230]. While in normal subjects 80 to 90 per cent of the fecal urobilinogen originates from destruction of red cells which have reached the end of their physiologic life span [65 230 233] (Figs 30-2 30-14) this does not apply to erythropoietic porphyria [65 210 230]. At least 31 per cent and in some patients as much as 80 per cent of the excreted urobilinogen is derived from sources other than circulating hemoglobin (Fig 30-15). Most of this urobilinogen fraction is excreted during the first 20 days after the administration of labeled glycine (Fig 30-15). That it is not derived from destruction of circulating erythrocytes is demonstrated by the fact that there is no concomitant fall in labeled hemoglobin heme.

The source of this early labeled urobilinogen fraction is obscure. It appears unlikely that nonhemoglobin heme such as myoglobin and other heme proteins contribute significantly to its formation [210 230 234]. It has been suggested that it may be derived from developing red cells which are destroyed in the marrow or shortly after their release into the circulation or alternatively that heme which is formed in excess of globin may be discarded and converted to bile pigments [234 93]. As a third possibility it may be suggested that the increase in the

Fig. 30-14 Concentration of  $^{15}\text{N}$  in fecal sterco-bilin of a normal subject given 1 gm glycine- $^{15}\text{N}$  (31.65 atom per cent excess  $^{15}\text{N}$ ) during the first 4 days of the experiment (By permission of C. H. Gray [30])

Fig. 30-15 Concentration of  $^{15}\text{N}$  in fecal sterco-bilin of a patient with erythropoietic porphyria given 1 gm glycine- $^{15}\text{N}$  (31.65 atom per cent excess  $^{15}\text{N}$ ) during the first 4 days of the experiment (By permission of C. H. Gray [30])

early labeled urobilinogen fraction may be related to the presence of two types of erythroid cells [15] as demonstrated in the fluorescence microscope. If it could be established that porphyrin containing erythrocytes have a much shorter life span than those which lack an increased pigment concentration, the observed pattern of bile pigment excretion would find a simple explanation. None of these hypotheses, however, is based on concrete experimental evidence.

#### CHEMICAL FINDINGS

The color of the urine of patients with erythropoietic porphyria may vary from a faint pink to a Burgundy red to a dark reddish brown depending upon the concentration of porphyrins. The amounts of uroporphyrin excreted are always increased and daily excretion of as much as 500 mg has been reported [13]. In addition, the urine contains large amounts of coproporphyrin, but the concentration is usually less than that of uroporphyrin [41, 203, 236]. Smaller amounts of porphyrins with seven, six, five, and three carboxyl groups have also been demonstrated [217, 227, 236]. Most of the urinary porphyrins are of the type I isomer [39, 63] but small fractions of uroporphyrin III have been identified [236, 237]. For coproporphyrin, the type I to type III isomer ratio may be as high as 99:1 [203] although small amounts of coproporphyrin III have been isolated in crystalline form [203].

PBG as identified by the conventional semiquantitative method [142] is consistently absent from the urine. Using more refined techniques, the daily excretion of PBG and of ALA in the urine is said to be within normal limits [227]. The feces regularly contain large amounts of coproporphyrin [13, 197, 203, 212, 220, 229] while the amount of uroporphyrin is much smaller [197, 203, 212]. Fecal excretion of protoporphyrin III (9a) though variable is usually not elevated. Most of the coproporphyrin is of type I isomer although small amounts of coproporphyrin III have been identified [197, 203].

Variable concentrations of uroporphyrin I and coproporphyrin I are regularly demonstrable in the plasma [41, 203, 212, 214]. Circulating erythrocytes contain high concentrations of uroporphyrin I [41, 203, 212, 214, 227] and somewhat lower concentrations of coproporphyrin I while for protoporphyrin III (9a) the values are usually not higher than those found in other hemolytic conditions [238]. Typical values in a patient studied before and after splenectomy are given in Table 30-2. Highest concentrations of these porphyrins are present in the bone marrow (Table 30-2) where the ratio of uroporphyrin I to coproporphyrin I is about the same as in the peripheral blood [41, 212, 227]. Most of the bone marrow porphyrins are present in developing erythroid cells (Fig. 30-11) [15, 203]. Uroporphyrin I in crystalline form has been isolated from bone marrow obtained by needle aspiration [41].

Fig. 30-14 Concentration of  $N^{15}$  in fecal sterolilin of a normal subject given 1 gm glycine- $N^{15}$  (31.65 atom per cent excess  $N^{15}$ ) during the first 4 days of the experiment (By permission of C. H. Gray [30])

Fig. 30-15 Concentration of  $N^{15}$  in fecal sterobilin of a patient with erythropoietic porphyria given 12 gm glycine- $N^{15}$  (31.65 atom per cent excess  $N^{15}$ ) during the first 4 days of the experiment (By permission of C. H. Gray [30])

system which converts PBG to uroporphyrinogen III [114 124 125] Preheating of the system to 60 C however results in loss of the ability to form the type III isomer PBG being converted *only* to uroporphyrinogen I [124 125]

In erythrocytes of patients with erythropoietic porphyria Rimington and Booy [130] and MacRae [239] demonstrated that ALA and PBG are converted to porphyrinogens of *both* type I and type III isomers Thus red cells in erythropoietic porphyria resemble *normal* human erythrocytes in which the ability to form porphyrins of type III isomer has been partly destroyed It is obvious that in porphyric erythrocytes the metabolic defect is only a partial one since complete inability to synthesize porphyrins of type III isomer would preclude the formation of hemoglobin a situation which would be incompatible with life In formation as to the relative amounts of the two porphyrin isomers formed in porphyric cells is not yet available

It might be expected that in maturing porphyric red cells the highest rate of synthesis of uroporphyrinogen I would coincide with the phase of most active hemoglobin formation As Thorell [240] has shown this occurs in the later stages of the developing normoblast Part of the uroporphyrinogen I synthesized in these cells is oxidized to uroporphyrin I while another fraction is decarboxylated to porphyrinogens with less than eight carboxyl groups mainly to coproporphyrinogen I which in turn is converted to coproporphyrin I (Fig 30 9) The factors which determine the relative amounts of the e type I porphyrins formed in porphyric red cells are not known but it would appear that the amount of coproporphyrin I formed may depend in part on the rate at which uroporphyrinogen I is oxidized to uroporphyrin I Since this process is photocatalytic [105] and is sensitized by the product uroporphyrin it may provide a possible explanation for the observation that some of the patients with erythropoietic porphyria are found to excrete more uroporphyrin during the summertime when they are exposed to sunlight [8 41 203]

The mechanism by which porphyrins are released from the cells is not understood A simple calculation based on the concentration of porphyrins in the circulating red cells indicates that release of porphyrins from hemolyzed erythrocytes could not account for more than a relatively small fraction of the excreted pigments [41] The high porphyrin content of bone marrow suggests that a major fraction of the porphyrins present in plasma and excreted in urine and bile may be derived from developing red cells This is supported by the observation that the most intense porphyrin fluorescence is found in immature red cells which still have their nuclei [15] (Fig 30-11) The erythroid hyperplasia of the bone marrow resulting from the increased rate of hemolysis further augments the formation of type I porphyrins [39 41 212 227] The beneficial

Large amounts of uroporphyrin I are also present in the spleen [41 202 203, 212 214 227] On fluorescence microscopic examination fine dustlike granules of porphyrin are visible in the red pulp but not in the Malpighian corpuscles [41, 202] In contrast to the marrow, splenic cells

do not exhibit nuclear fluorescence [41] In the liver red fluorescence is minimal but considerable amounts of uroporphyrin I are demonstrable on extraction [41 202 212 214]

#### NATURE OF THE METABOLIC DEFECT

The findings discussed in the preceding sections indicate that in erythropoietic porphyria the primary defect probably involves overproduction of porphyrins of type I isomer for which the body has no use The defect appears to be confined to the hematopoietic system [15 41, 128 230] and may involve only part of the erythroid cells [15 202] Thus Fischer's original concept [59] that porphyrins of type I isomer are synthesized along with and parallel to hemoglobin formation appears to be essentially correct

As seen in Figs 30-8 30-9 the most likely site for the metabolic defect is in the enzymatic mechanism which converts PBG to uroporphyrinogen It may be recalled that PBG deaminase converts PBG only to uroporphyrinogen I whereas formation of uroporphyrinogen III requires the combined action of PBG deaminase and uroporphyrinogen isomerase It would appear that either overactivity of PBG deaminase or a defect in uroporphyrinogen isomerase would account for the increased formation of uroporphyrinogen I at the expense of the type III isomer [113 117] It has been noted that the latter enzyme is relatively heat labile [113, 114 117] Human red cell hemolysates contain the complete enzymatic

patients are homozygous for the trait. The sexes are equally affected. The lack of increased porphyrin excretion in parents and in normal siblings of patients [217-225] suggests that individuals who are heterozygous for the trait do not exhibit the metabolic abnormality. Thus the mode of inheritance of erythropoietic porphyria appears to be autosomal recessive.

#### CONGENITAL PORPHYRIA IN OTHER MAMMALS

**Cattle.** Congenital porphyria has been observed in cattle in South Africa, Denmark, England, and the United States [212, 244-247]. In all instances the disease was inherited as a simple Mendelian recessive characteristic. Heterozygous animals are clinically and biochemically normal [212, 246, 247]. Porphyric calves were obtained by breeding animals which were known to be heterozygous for the trait [212, 248].

Afflicted animals exhibit photosensitivity of those areas of the skin which are not pigmented or covered with dark hair [212, 248]. The first case of bovine porphyria recognized in Denmark was discovered because

the cow was not getting on at pasture but did well in the stable. When the animals are slaughtered, bones and teeth are found to be dark and to contain a large amount of porphyrin [212, 244, 246, 248]. The bovine form of congenital porphyria appears to have distinct similarities to the human disease. Anemia, reticulocytosis, and splenomegaly may be present [212], but splenectomy performed in one porphyric cow failed to result in significant improvement [212]. The spleen contained much porphyrin, mostly uroporphyrin I; the porphyrin concentration in the liver was insignificant [212, 247]. As in the human disease, highest porphyrin concentrations were found in the bone marrow [212], and on fluorescence microscopic examination unstained bone marrow preparations exhibited intense porphyrin fluorescence, which was most prominent in normoblastic nuclei. On staining, these cells exhibited abnormalities of nuclear structure similar to those described in human porphyria (Figs 30-11, 30-13). In contrast to what occurs in the human disorder, circulating erythrocytes contained relatively little uroporphyrin and coproporphyrin, but much protoporphyrin [212]. While most of the uroporphyrin and coproporphyrin in bone marrow and circulating erythrocytes was of type I isomer [212], the isomer type of the protoporphyrin has not yet been determined. It is conceivable that the high protoporphyrin content of bovine red cells may be due in part to formation of protoporphyrin I. If further studies should confirm this hypothesis, it would be the only instance in which protoporphyrin of type I isomer has been demonstrated in nature. It would further indicate that bovine erythrocytes must be capable of decarboxylating coproporphyrinogen I, an enzymatic mechanism lacking in red cells of the other species studied.

effect of splenectomy observed in some of the cases may be due to a reduction in the rate of hemolysis and hence in erythroid hyperplasia which results in reduced porphyrin formation [39]

### HEREDITARY CONSIDERATIONS

It was assumed by Carrod [241] and by Guenther [13] that erythropoietic porphyrin is an inborn error of metabolism probably inherited as a Mendelian recessive character. The data presently available support this belief but they do not bear out the additional claim that the condition is more common in the male [13, 242]. In fact of the 41 cases listed in Table 30-1, 24 were female and only 17 male. As noted earlier the apparent male predominance in earlier statistics [185] was probably due to the erroneous inclusion of cases of porphyria cutanea tarda which occurs more frequently in males [16].

Of the 41 cases listed in Table 30-1, 16 were observed in families with at least 2 cases [8, 199, 200, 208, 216, 218, 224-226] and in 2 instances 3 cases were reported in the same family, all occurring in a single generation [208, 210-217]. In addition in 5 families, 6 siblings of patients with erythropoietic porphyrin were reported to have died in infancy exhibiting features which may have been porphyrin (these are not included in Table 30-1) [9, 191, 195, 203, 213, 214]. Even without statistical analysis these data clearly show that erythropoietic porphyrin not uncommonly occurs in siblings, a finding which is contrary to a recent statement by Waldenström [16].

In 19 of the cases the family history was reported in sufficient detail to permit estimation of the number of unaffected siblings. The 19 patients with porphyrin were found to have 52 siblings who did not exhibit the disease, a ratio which closely approximates that predicted if the abnormality is inherited as an autosomal recessive gene. In 3 instances, 2 out of 4 siblings were affected [199, 200, 224, 225] whereas in 1 family only 1 out of 12 children had porphyrin [218]. In 3 of the reported families consanguinity of the parents was recorded [194, 200, 219].

The disease has never been observed in successive generations but reproduction is almost nil [16]. The patient reported by Hench et al [197] gave birth to two apparently normal children, one of whom is alive, the other died shortly after a premature delivery. During the first few days of life the living baby excreted considerable amounts of porphyrins which were believed to have been passively transferred through the placenta. This is the only instance in which pregnancy has been reported in a patient with erythropoietic porphyrin. In addition the healthy wife of the famous case Petry had two spontaneous abortions, each in the fourth month of pregnancy [243]. The fetuses were carefully studied but no abnormalities of pigment metabolism were detected [243].

On the basis of the findings it appears probable that porphyrin

patients are homozygous for the trait. The sexes are equally affected. The lack of increased porphyrin excretion in parents and in normal siblings of patients [217-225] suggests that individuals who are heterozygous for the trait do not exhibit the metabolic abnormality. Thus the mode of inheritance of erythropoietic porphyria appears to be autosomal recessive.

#### CONGENITAL PORPHYRIA IN OTHER MAMMALS

**Cattle** Congenital porphyria has been observed in cattle in South Africa, Denmark, England, and the United States [212, 244-247]. In all instances the disease was inherited as a simple Mendelian recessive characteristic. Heterozygous animals are clinically and biochemically normal [212, 246, 247]. Porphyric calves were obtained by breeding animals which were known to be heterozygous for the trait [212, 248].

Afflicted animals exhibit photosensitivity of those areas of the skin which are not pigmented or covered with dark hair [212, 248]. The first case of bovine porphyria recognized in Denmark was discovered because the cow was not getting on at pasture but did well in the stable. effect of splenectomy observed in some of the cases may be due to a reduction in the rate of hemolysis and hence in erythroid hyperplasia which results in reduced porphyrin formation [39]

### HEREDITARY CONSIDERATIONS

It was assumed by Garrod [241] and by Guenther [13] that erythropoietic porphyria is an inborn error of metabolism probably inherited as a Mendelian recessive character. The data presently available support this belief but they do not bear out the additional claim that the condition is more common in the male [13, 242]. In fact, of the 41 cases listed in Table 30-1, 24 were female and only 17 male. As noted earlier the apparent male predominance in earlier statistics [188] was probably due to the erroneous inclusion of cases of porphyria cutanea tarda which occurs more frequently in males [16].

Of the 41 cases listed in Table 30-1 16 were observed in families with at least 2 cases [8 199, 200 208 215, 216 224-226] and in 2 instances 3 cases were reported in the same family, all occurring in a single generation [208 215-217]. In addition in 5 families 6 siblings of patients with erythropoietic porphyria were reported to have died in infancy exhibiting features which may have been porphyria (these are not included in Table 30-1) [8 191 195 203 213 214]. Even without statistical analysis the data clearly show that erythropoietic porphyria not uncommonly occurs in siblings a finding which is contrary to a recent statement by Waldenstrom [10].

In 19 of the cases the family history was reported in sufficient detail to permit estimation of the number of unaffected siblings. The 19 patients with porphyria were found to have 52 siblings who did not exhibit the disease a ratio which closely approximates that predicted if the abnormality is inherited as an autosomal recessive gene. In 3 instances 2 out of 4 siblings were affected [199 200 224 225] whereas in 1 family only 1 out of 12 children had porphyria [218]. In 3 of the reported families consanguinity of the parents was recorded [194 200, 219].

The disease has never been observed in successive generations but reproduction is almost nil [15]. The patient reported by Kench et al [197] gave birth to two apparently normal children one of whom is alive, the other died shortly after a premature delivery. During the first few days of life the living baby excreted considerable amounts of porphyrins which were believed to have been passively transferred through the placenta. This is the only instance in which pregnancy has been reported in a patient with erythropoietic porphyria. In addition the healthy wife of the famous case Petry had two spontaneous abortions each in the fourth month of pregnancy [243]. The fetuses were carefully studied but no abnormalities of pigment metabolism were detected [243].

On the basis of these findings it appears probable that porphyric

## HEPATIC FORMS OF HUMAN PORPHYRIA

## INTRODUCTION AND CLASSIFICATION

Although in congenital erythropoietic porphyria the metabolic defect can be traced to the developing red cells in the bone marrow where an abnormality in heme biosynthesis accounts for the overproduction of porphyrins of type I isomer such a relationship cannot be demonstrated in the other and more frequently encountered forms of human porphyria. Such patients show no hematologic disorder [18 128] and the porphyrin content of bone marrow and circulating erythrocytes is invariably normal [41 128]. The only organ consistently exhibiting high concentrations of porphyrins or porphyrin precursors or both is the liver [18 28 41 55-59 128 185]. On the basis of these observations it has been proposed to group the latter forms of porphyria together under the heading *hepatic porphyria* as contrasted with the erythropoietic form [18 39 41]. This should not be considered as a final and unalterable classification; it would be much preferable to describe each form of the disease in terms of the metabolic defect involved. Since this stage of knowledge has not yet been reached it appears at least desirable to make a clear distinction between erythropoietic porphyria on one hand and the other less well-defined disorders of porphyrin metabolism on the other hand.

In the hepatic forms of porphyria not only does the liver contain much porphyrin and many porphyrin precursors but impairment of hepatic function or outspoken liver disease is frequent [39 41]. In fact in the photosensitive types of hepatic porphyria liver disease may be so severe as to make it difficult to decide whether the disturbance in porphyrin metabolism is the result of a genetically controlled defect or is a manifestation of advanced hepatic disease [16 38 42 128 137]. This is particularly true of those patients in whom there is no evidence for a familial occurrence of the disorder [38 40 42 43 254 255]. As mentioned earlier there is also reason to believe that a syndrome resembling acute porphyria may develop in supposedly normal persons as a result of addiction to sedatives of the sulfonal and Sedormid group [13 24 26-28 34 36 256]. One may question whether such cases should not better be designated as *porphyrinuria* reserving the term *porphyria* for clearly inherited forms of the disorder. However since in many instances it may be impossible to rule out with certainty a preexisting but unrecognized abnormality of pyrrole metabolism such a distinction would be arbitrary and might better be postponed until more is known of the basic defects involved.

To this problem in deciding whether the metabolic disturbance is inherited or acquired is added the present confusion surrounding the classification of porphyria [16 17 39 137]. Many attempts at a classification acceptable from all standpoints—clinical chemical genetic and

The urine of porphyric cattle contains much uroporphyrin I and smaller amounts of coproporphyrin I [157 212 246 248] in the feces this ratio is reversed [157 212] PBG is usually not demonstrable in the urine nor could it be detected in the liver of an afflicted animal [212, 247 248] It is apparent that bovine congenital porphyria like its human counterpart is characterized by overproduction of porphyrins of type I isomer in cells of the erythroid series The recent finding by Rimington's group [180] that incubation of PBG with hemolyzed erythrocytes obtained from porphyric cattle resulted in formation of both uroporphyrinogen I and uroporphyrinogen III suggests that the metabolic defect in the bovine disease may be similar to that in human porphyria

**Pigs** Congenital porphyria is also observed in pigs [157 246 248 249] but in contrast to the human and bovine forms the porcine disease is probably inherited as a Mendelian dominant trait [157, 246] although further studies on the precise mode of inheritance are necessary Porphyric pigs excrete in the urine large amounts of uroporphyrin and smaller quantities of coproporphyrin and of porphyrins with seven six and five carboxyl groups, the feces contain mostly coproporphyrin [249] Almost all the excreted porphyrins belong to the type I isomer series [157] porphobilinogen is not demonstrable [246] Affected pigs do not exhibit photosensitivity, and the diagnosis rests mainly on the discovery of red fluorescence in bones and teeth Teeth of newborn pigs with porphyria contain considerable amounts of uroporphyrin I [157 246] a finding which serves as a convenient mode of diagnosis during lifetime [246]

Little is known of the biochemical nature and the anatomic site of the metabolic defect It remains to be shown whether the overproduction of porphyrins of type I isomer occurs in erythroid cells as in the human and bovine forms of the disease or whether the pigments are derived from other sites Chemical and microscopic studies of bone marrow have not yet been reported but With [157] observed high concentrations of porphyrins in the spleen and much smaller amounts in liver kidneys and blood Pigs affected with the disease appear to show a considerable degree of fluctuation in the amounts of porphyrins produced [157] In some instances where high concentrations of uroporphyrin were demonstrated in the teeth at birth no evidence for a disturbance in porphyrin metabolism was detectable a few months later at autopsy [157] This has been taken to indicate that the porcine form of porphyria may show a high degree of latency [157] a factor which renders genetic studies very difficult

**Other Species** Finally it should be noted that in at least two species the fox squirrel (*Sciurus niger*) and the touraco bird (*Musophagidae*) uroporphyrin is a physiologic end product of metabolism [250-253] The metabolic origin of the pigment in these species is not known

[16 39] These manifestations are characteristically intermittent in nature. Acute attacks may last from several days to many months. Between acute episodes periods of remission occur during which symptoms may be slight or even absent [18].

Neurologic manifestations are extremely variable. They may involve peripheral nerves, autonomic nervous system, brain stem, cranial nerves, or cerebral function. Extensive reviews of the neurologic and neuropathologic findings have recently been published [16 18 20 187 262 263]. As noted earlier, the relationship of porphyrins and porphyrin precursors to the disturbances of the nervous system is not clear. It is noteworthy that at autopsy the brain and the spinal cord of patients with porphyria usually fail to exhibit PBG or increased concentrations of porphyrins [41 187, 264].

Many of these patients have hypertension, but this is not always present and at times the blood pressure may actually be low [265]. Photosensitivity and increased mechanical fragility of the skin are lacking. The gastrointestinal manifestations frequently lead to weight loss and occasionally to severe emaciation, while prolonged vomiting may cause oliguria and azotemia. Death usually occurs from respiratory paralysis, but uremia and cachexia may be contributing factors.

In many instances the metabolic defect may be present in a latent form so that afflicted persons are entirely free of symptoms or exhibit only vague complaints such as dyspepsia or nervousness [14 16 39]. In such patients careful analysis of the urine frequently reveals excretion of increased amounts of PBG or ALA or both [16 19 39 137]. Latent porphyria may never become clinically manifest or acute attacks may occur at a later date. In patients with latent porphyria acute attacks may be precipitated by the administration of various compounds, notably barbiturates, sulfonamides, and anesthetics [14 20 39]. This is however not an invariable sequence of events, as the author has repeatedly observed patients with latent porphyria who underwent major surgery under general anesthesia without developing symptoms of porphyria.

In most instances acute attacks, unless terminating fatally, are followed by periods of latency during which only a careful search for abnormal urinary metabolites may reveal the presence of the metabolic disturbance. It is not uncommon that during latency the conventional qualitative test for PBG [142] may become negative [16 39] and the diagnosis must be established by quantitative analysis for PBG and ALA [19].

### *Chemical Findings*

The most characteristic finding in this type of porphyria is the urinary excretion of large amounts of PBC [14 266]. As has been discussed, PBG

pathogenetic—have provided little clarification [13 16 23 39 41, 131, 182 257] The reasons for this failure are twofold In the first place one and the same term has often been used to describe syndromes with widely varying symptomatology This is best exemplified by considering the different meanings which *porphyria cutanea tarda* has been given by different investigators The term as originally coined by Waldenström in 1937 [14] was used to describe patients in whom porphyrinuria and photosensitivity developed late in life in the absence of abdominal and neurologic symptoms Today, however, the same author distinguishes three or possibly four different types of *porphyria cutanea tarda* [16] while others [18, 39 41] still use the term in its original restricted sense In addition Rimington [17] states that 'in this condition [*porphyria cutanea tarda*] abdominal and neurological manifestations may be the most prominent features while the skin may be insignificantly affected or indeed appear quite normal' It is obvious that this lack of unanimity in terminology has handicapped the search for a satisfactory classification [40]

A second factor contributing to the present confusion was the discovery that in the same family a genetically controlled disturbance of porphyrin metabolism could give rise to clinical manifestations of widely varying nature, including abdominal neurologic or cutaneous symptoms [187 258] A purely descriptive classification of such a metabolic disturbance is obviously inadequate In the following discussion an attempt will be made to consider the various forms of hepatic porphyria as they appear in genetically homogeneous groups Such an approach meets with a number of limitations the most serious of which is the present ignorance regarding the precise nature of the metabolic defect

#### SWEDISH TYPE OF PORPHYRIA

##### *Clinical Manifestations*

The most extensive study of this type of familial porphyria was undertaken by Waldenström in 1937 [14] although many similar cases had been reported previously [18] The condition has been described as acute porphyria [18 14 16] or as intermittent acute porphyria [18]

Abdominal pain of moderate to severe degree and often colicky in nature is the initial and frequently the most prominent symptom The pain may be generalized or localized but the abdomen is usually soft, and tenderness is not marked Rebound tenderness is lacking A ray examination frequently reveals areas of intestinal distention proximal to areas of spasm [259] Constipation is usually marked and may give rise to confusion with bowel obstruction [260 261] Distention of the stomach and pernicious vomiting are at times outspoken Slight fever leukocytosis, and tachycardia may occur but are not universally present

[16 39] These manifestations are characteristically intermittent in nature. Acute attacks may last from several days to many months. Between acute episodes periods of remission occur during which symptoms may be slight or even absent [18].

Neurologic manifestations are extremely variable. They may involve peripheral nerves, autonomic nervous system, brain stem, cranial nerves, or cerebral function. Extensive reviews of the neurologic and neuropathologic findings have recently been published [16 18 20 187 262 263]. As noted earlier, the relationship of porphyrins and porphyrin precursors to the disturbances of the nervous system is not clear. It is noteworthy that at autopsy the brain and the spinal cord of patients with porphyria usually fail to exhibit PBG or increased concentrations of porphyrins [41 187 264].

Many of these patients have hypertension, but this is not always present and at times the blood pressure may actually be low [265]. Photosensitivity and increased mechanical fragility of the skin are lacking. The gastrointestinal manifestations frequently lead to weight loss and occasionally to severe emaciation, while prolonged vomiting may cause oliguria and azotemia. Death usually occurs from respiratory paralysis, but uremia and cachexia may be contributing factors.

In many instances the metabolic defect may be present in a latent form so that afflicted persons are entirely free of symptoms or exhibit only vague complaints such as dyspepsia or nervousness [14 16 39]. In such patients careful analysis of the urine frequently reveals excretion of increased amounts of PBG or ALA or both [16 19 39 187]. Latent porphyria may never become clinically manifest or acute attacks may occur at a later date. In patients with latent porphyria acute attacks may be precipitated by the administration of various compounds, notably barbiturates, sulfonamides, and anesthetics [14 20 39]. This is however not an invariable sequence of events, as the author has repeatedly observed patients with latent porphyria who underwent major surgery under general anesthesia without developing symptoms of porphyria.

In most instances acute attacks, unless terminating fatally, are followed by periods of latency during which only a careful search for abnormal urinary metabolites may reveal the presence of the metabolic disturbance. It is not uncommon that during latency the conventional qualitative test for PBG [142] may become negative [16 39] and the diagnosis must be established by quantitative analysis for PBG and ALA [19].

#### *Chemical Findings*

The most characteristic finding in this type of porphyria is the urinary excretion of large amounts of PBG [14 266]. As has been discussed, PBG

is an obligatory intermediate in the biosynthesis of porphyrins and of heme and small amounts of it are normally excreted in the urine. It is a colorless monopyrrolic chromogen giving an intense red color with Ehrlich's aldehyde (*p*-dimethylaminobenzaldehyde); it has a strong absorption band at 560 m $\mu$  and a weaker one at 525 m $\mu$  [123]. In contrast to the red compound obtained with urobilinogen, the Ehrlich aldehyde compound of PBG is not extractable with chloroform [123]. The concentration of PBG present in normal urine is too small to be detected with the conventional method [143] described by Watson and Schwartz [142]. During acute attacks of porphyria, however, the test is strongly positive and a positive result is usually, but not invariably, obtained during latency. Estimation of PBG excretion during acute manifestations has yielded values ranging from less than 30 to 176 mg per liter urine [187] and from 50 to 170 mg per day [37, 136]. During periods of latency these values may be much lower [19, 37, 137].

In addition to PBG, the urine usually contains large amounts of ALA, another obligatory intermediate in the biosynthesis of heme. During an acute episode, the urine may contain as much as 180 mg ALA per day [37, 136, 137]; during remission the values may be much lower [37, 137].

Although the urinary excretion of large amounts of these two compounds is a typical feature of this form of porphyria, the urine may also contain other porphyrin precursors which give a negative Ehrlich reaction [39, 159-161, 267]. Some of these chromogens are undoubtedly porphyrinogens or their partially oxidized derivatives, porphomethene and porphodimethene (Fig. 30-10). In the urine, all these porphyrin precursors, including PBG and possibly ALA, can be converted to porphyrins [121, 144, 162], but the extent of this process and the nature of the porphyrins obtained depends largely on external factors such as pH, exposure to light and air, and presence of oxidizing substances [121, 122, 128, 144, 268]. Freshly voided urine of patients with acute porphyria may contain little if any increase in uroporphyrin concentration [122]; porphyrins are formed only on standing or during the extraction procedure. This is probably why freshly passed urine frequently is of normal color but darkens on standing in light and air [123]. It should be noted, however, that the color is not all due to porphyrins but in part reflects formation of porphobilin, a brown amorphous oxidation product of PBG [123].

The many extensive studies which have been undertaken in an attempt to define more clearly the nature of the porphyrins present in the urine of patients with acute porphyria or formed on standing [14, 56-58, 122, 162, 268-272] have yielded seemingly controversial results. One can probably reconcile these different findings by realizing that most of the isolated porphyrins are actually formed after the urine has been passed and thus are largely artifactual [121, 122]. There is little doubt that

uroporphyrin of both isomer types is present but the isomer ratio appears to be influenced by the conditions under which precursors are converted to porphyrins. A curious and as yet unexplained finding is that most of the porphyrins are present as metal complex the metal probably being zinc [18-172]. This is in contrast to erythropoietic porphyria where uroporphyrin I is largely excreted in its free form.

Few data are available on porphyrin excretion in the stool. Uroporphyrin has been isolated but the concentration does not appear to be

TABLE 30-3 UROPORPHYRIN CONCENTRATIONS IN LIVER AND URINE BEFORE AND AFTER CONVERSION OF PRECURSORS IN PATIENTS WITH THE SWEDISH TYPE OF PORPHYRIA

very high [39-41, 58-278]. Fecal excretion of coproporphyrin and protoporphyrin is little if at all increased [15~].

With the exception of the liver tissues obtained at autopsy, usually fail to reveal increased porphyrin concentrations [14, 18, 23, 41, 55, 57, 58, 128]. In some cases uroporphyrin or coproporphyrin or both have been identified and isolated from hepatic tissue [41, 47, 68] but this is not possible in all instances [54]. More important is the demonstration that the liver regularly contains large amounts of PBG [41, 56, 57] while in other organs including the spleen, muscle and in bone marrow this precursor has not been detected [41, 56]. Biopsy studies performed on a larger group of patients with acute or latent porphyria showed that fresh liver tissue contained only insignificant amounts of porphyrins but that a marked increase in uroporphyrin concentration could be obtained after converting precursors to porphyrins (Table 30-3) [41].

These findings indicate that in the Swedish type of porphyria the principal metabolic abnormality is the presence and excretion not of porphyrins but of *porphyrin precursors*. The large quantities of ALA, PBG, and other porphyrin precursors excreted in the urine are probably derived from the liver since this is the only organ in which they can be demonstrated. It appears unlikely that these compounds could have reached the liver from other sites since injection of ALA and PBG does not lead to accumulation of these compounds in the liver of experimental animals [146].

### *Possible Nature of the Metabolic Defect*

If the major biochemical defect in this form of porphyria is assumed to involve overproduction of ALA and PBG, two possible mechanisms have to be considered which could give rise to this metabolic derangement. It is conceivable that the biosynthesis of some heme-containing compound may be blocked and that increased pyrrole formation would result from an attempt by the liver to overcome this block [110]. Alternatively, the defect could be at the ALA level resulting either in increased formation of this compound or in interference with one or more of its metabolic pathways of disposition.

Little formation is available to support the first of these two hypotheses. As noted earlier, the liver contains a number of heme proteins, some of which appear to have a relatively rapid turnover. The metabolism of these compounds has not been investigated in porphyria. In experimental porphyria produced in animals by Sedormid, inhibition of catalase synthesis in the liver has been demonstrated [35], but it is not known how this defect is related to the overproduction of porphyrins and of porphyrin precursors [36]. In human porphyria, the few determinations of liver catalase activity have failed to reveal a significant decrease in enzymatic activity [56, 177]. A further argument against the concept of a block in heme protein synthesis is the absence of significantly increased concentrations of coproporphyrin and protoporphyrin [41]. Increased formation of these compounds would be expected if one of the final steps of heme biosynthesis were blocked (Fig. 30-8).

The second hypothesis, which assumes a defect of formation or metabolism of ALA, is consistent with preliminary findings obtained in studying the pool size and disposition of ALA and PBG [82, 274]. The percentage of labeled ALA converted to urinary PBG was found to be several times greater in porphyria than in normal subjects (Fig. 30-16) [82]. This may indicate an adaptive increase in activity of ALA dehydrase in the liver, but direct evidence for this has not yet been obtained. Moreover, the apparent dilution of administered ALA and of PBG suggested that in porphyria the pools of these compounds are increased (Table 30-4). If this is not simply because of altered permeability of the cells for ALA

it may indicate either an increase in formation of ALA or a decrease in one or more of the nonporphyrin pathways by which this compound can be metabolized (Fig 30-5) [82]

Fig 30-16 Conversion of  $\delta$ -aminolevulinic acid (ALA) to porphobilinogen (PBG) by a normal man and by a patient with acute porphyria. Both were given a dose of 1 gm ALA per 65 kg body weight. Excretion of PBG = expressed as percentage of ALA administered. (By permission of J J Scott [81])

Direct support for this hypothesis is difficult to obtain. It has been observed that in experimental Sideroid porphyria increased formation of porphyrins is associated with decreased purine synthesis [87], a finding which may suggest that an additional amount of ALA is channeled towards PBG production. Similar studies in human porphyria have not yet been reported.

In *R. spheroides* Shemin and his coworkers [87] have recently obtained evidence for a heat labile inhibitor of ALA synthesis. It was observed that extracts of *R. spheroides* cells grown aerobically in the dark are far

less active for ALA synthesis than extracts obtained from cells grown anaerobically in the light. More important still is the finding that formation of ALA is inhibited when extracts of aerobically dark grown cells are added to extracts from anaerobically light grown cells. This suggests that at the step of ALA synthesis, the cell may possess a regulatory mechanism by which porphyrin and heme biosynthesis can be controlled [87]. If it is permissible to extrapolate these findings to those in acute porphyria, one may speculate that patients with this disease may have a defect involving this regulatory mechanism [87]. Such a disturbance could be limited to the liver or it could be more extensive and include for example, the central nervous system. In the latter case a possible explanation would be provided for the protean nature of the neurologic findings and the patchy anatomic lesions [121]. Proof for these speculations must of course await further investigations.

As noted before increased excretion of ALA and PBG may be detected in asymptomatic carriers of the disease. Furthermore acute attacks of porphyria may be followed by periods of complete symptomatic remission. During latency such patients usually continue to excrete abnormal amounts of PBG and ALA [19-137] but at times the concentration of these metabolites in the urine may return to values scarcely above normal [16-19-39]. This explains not only why during periods of latency patients may be asymptomatic but why it may be difficult to uncover their metabolic derangement. The factors responsible for this fluctuating course are poorly understood although it is well known that barbiturates, sulfonamides and related compounds may exert an aggravating effect [14-20-39].

It has also been noted that the age of onset of symptoms is usually at or shortly following puberty (Fig. 30-17) [16]. manifest porphyria is exceedingly rare before puberty [39-276-278]. In children of afflicted kinships even the presence of latent porphyria is often difficult to detect before adolescence [19]. Furthermore the death rate for porphyria is highest in young adults [16]. These observations indicate that the metabolic defect even though it is inherited may not become clinically apparent until puberty and that symptomatic manifestations are most pronounced during the early part of the reproductive period.

A possible relationship between porphyrin metabolism and gonadal activity is apparent but its nature is not known. In female patients, periodic exacerbations of the disease are sometimes correlated with the menstrual cycle. The author has followed a young woman in whom severe abdominal pain and intestinal obstruction regularly recurred during the premenstrual phase and terminated abruptly with the onset of vaginal flow. For the last 4 years as menstruation has been suppressed by androgenic therapy the patient has remained entirely free of symptoms [177]. The effect of pregnancy on porphyria is unpredictable [279]. In

Fig 30-17 Age at first clinical manifestation of Swedish type of porphyria. (By permission of J Waldenström [16])

several instances relapses have occurred during or shortly following delivery [18-39]

### *Heredity and Incidence*

Waldenström's extensive study in Sweden [14, 16, 230] has shown that a positive family history could definitely be established for 243 of 321 proved cases of porphyria. One hundred and thirty seven cases belonged to a single family. The three next largest families contained 14, 12, and 9 porphyric members, respectively. On the basis of these findings, it has been assumed that the metabolic defect is inherited as a Mendelian dominant trait [14, 16, 230]. The frequency with which the disturbance remains asymptomatic and the fact that even genetically certain carriers may fail to exhibit an easily detectable increase in PBG excretion render genetic studies very difficult. A representative pedigree from the Swedish study is given in Fig 30-18. The youngest generation comprised largely

■ ● CLINICAL AND/OR CHEMICAL EVIDENCE OF PORPHYRIA

Fig 30-18 Pedigree of a family with the Swedish type of porphyria. Urine of clinically normal individuals was examined with the semiquantitative method for porphobilinogen. It is probable that with the advent of refined methods for estimation of urinary porphobilinogen and  $\delta$ -aminolevulinic acid, more cases of latent porphyria will be discovered. This applies particularly to the fifth generation, which is comprised largely of children [13] (By permission of J. W. Odell and Sm. [16]).

of children : cannot be adequately evaluated because quantitative determinations of PBG and ALA excretion have not yet been reported [19] The occurrence of the disease in several successive generations is a strong indication for its dominant mode of inheritance [16]

Familial occurrence of acute porphyria has been reported by other investigators Watson [39] studied 97 cases and Markovitz [263] collected from the literature 69 cases of acute porphyria many of which had a positive family history Acute attacks of porphyria were observed in two pairs of identical twins [16 231] In earlier studies marked predilection for the female sex was reported [14] Later reports however based on a larger amount of case material yielded a female to male ratio of 3.2 [16 39 263] Latent porphyria on the other hand appeared to be more frequent in males [39] This is consistent with the concept that the metabolic disturbance is inherited as a Mendelian dominant trait but more frequently produces symptoms in young adults of female sex

The incidence of the disease obviously is influenced by its occurrence in large families For Lapland for example Waldenstrom [16] has calculated an incidence of 1/1 000 largely because a single family with no less than 137 known porphyric persons lives in this northern province On the other hand for Sweden proper the incidence is about 1/5 100 000 Judging from the number of reported cases in the literature it would appear that the disease is more frequent in individuals with Scandinavian or English ancestry while in Negroes its occurrence is extremely rare [282 283]

### *Recapitulation*

The Swedish type of hepatic porphyria is characterized by abdominal and neurologic symptoms which are frequently intermittent in nature Cutaneous manifestations are lacking The abnormality is believed to be inherited as a Mendelian dominant trait but afflicted individuals may be free of symptoms Qualitative methods of investigation may fail to reveal the metabolic derangement in asymptomatic persons who are genetically certain carriers

The defect almost certainly involves overproduction of the porphyrin precursors ALA and PBG Increased excretion of porphyrins is variable and may be absent

It has been pointed out [16 137] that acute porphyria and intermittent acute porphyria are synonyms for this condition for the disease is based on a genetically controlled metabolic disorder of chronic nature Furthermore the primary disturbance probably does not involve porphyrin metabolism but occurs at the level of pyrrole biosynthesis which is interrelated with the tricarboxylic acid cycle In future revisions of nomenclature the e factors must be taken into consideration

## SOUTH AFRICAN TYPE OF PORPHYRIA

*Clinical Manifestations*

Dean [284] and Dean and Barnes [137, 258] have studied a large group of porphyric patients in the white population of South Africa. In 13 families a total of 236 porphyric persons were discovered, all of whom could be traced back to a pair of early settlers who immigrated from Holland and married at the Cape of Good Hope in 1688 [258]. Many of these patients exhibit cutaneous manifestations, most pronounced on the hands and face. The skin is sensitive to both sunlight and mechanical trauma, and abrades easily with occasional blister formation. In some of the afflicted individuals skin sensitivity may be slight and intermittent. Cutaneous manifestations are often the only symptoms in men who feel otherwise well throughout life. In some members of this population acute attacks with abdominal pain and paralysis may occur; they are frequently precipitated by barbiturates or anesthetics.

In women skin sensitivity is usually slight, but it may be more pronounced during pregnancy. They are likely to develop recurrent attacks of abdominal pain which may simulate an acute surgical emergency. These patients are usually emotionally unstable, but the diagnosis of porphyria is seldom made before an acute attack of porphyria has occurred. This is likely to happen at some time during adult life and is nearly always precipitated by drugs, especially barbiturates. During an acute episode abdominal pain becomes more severe, peripheral and bulbar paresis may appear, and respiratory paralysis may result in coma and death. Associated with these manifestations is evidence of marked impairment of liver function and excretion of large amounts of PBG and porphyrins in the urine. Acute attacks rarely occur before the age of 16 and are seldom observed after 50; photosensitivity is occasionally present at an earlier age [285]. In many of these persons the disease remains latent throughout life, or abdominal and cutaneous symptoms may be so mild as not to come to a physician's attention.

*Chemical Findings*

In this form of porphyria the characteristic finding is the continuous excretion of large amounts of coproporphyrin and protoporphyrin in the feces. In normal persons upper limits of fecal porphyrin concentration are assumed to be 15 [137] to 20  $\mu\text{g}$  [17] for coproporphyrin and 30 [137] to 45  $\mu\text{g}$  [17] for protoporphyrin, all expressed per gram of dry weight. As seen in Table 30-5, in patients with South African porphyria the concentration of these porphyrins in the feces is greatly increased [137, 220]. Fecal excretion of porphyrins is elevated even though the patients may be in clinical remission or may have been asymptomatic all their lives.

[137] Furthermore increased porphyrin concentration in the stool is demonstrable in asymptomatic children of patients with porphyria [220] As seen in Table 30.6 14 out of 35 such children under the age of 18 were found to have elevated values. It is assumed that these children have latent porphyria which may become manifest during adult life [220]

Occasionally photosensitivity is already present during adolescence [283]. In such instances the finding of increased protoporphyrin excretion in the stool may help to differentiate this disorder from erythropoietic porphyria [220].

During clinical remission or in patients with latent porphyria the excretion of porphyrins in the urine may not be significantly increased [137] although exact estimation and analysis of the urinary pigments has not yet been reported. During acute episodes urinary porphyrin excretion is usually much increased [137, 208]. More important is the finding that in patients with acute or subacute symptoms the urine

regularly contains large amounts of ALA and PBG (Table 30.5) while during remission, the excretion of these compounds may return to normal values [137]. As a rule, the occurrence of abdominal and neurologic mani-

festations appears to be associated with urinary excretion of porphyrin precursors while increased fecal excretion of porphyrins is present at all times apparently unrelated to the presence or absence of clinical symptoms.

#### Comparison with Other Forms of Porphyria

The high fecal excretion of coproporphyrin and protoporphyrin by white patients in South Africa clearly differentiates this form of porphyria from that studied by Waldenström in Sweden [14, 16, 137]. In the latter group of patients fecal porphyrin excretion is either within normal limits or only moderately increased [137]. In an earlier study it had been suggested that the absence of cutaneous symptoms in Sweden and their presence in male patients in South Africa may be related to increased exposure to sunlight and to mechanical trauma [258]. In a more recent investigation however Dean et al. [137] found Swedish patients whose symptomatology and excretory pattern resemble those seen in South Africa, in that cutaneous symptoms are prominent and the feces contain large amounts of coproporphyrin and protoporphyrin. In South Africa on the other hand a group of patients of British stock, who did not have South African ancestry were found to have features similar to those in the large Swedish families in that cutaneous manifestations are absent and fecal porphyrin excretion is only slightly increased [137]. Furthermore in Holland these authors studied two porphyric families, of which one resembles the South African cases and the other has many features of the disturbance present in the Swedish families [137]. These observations seem to indicate that the differences in clinical and bio-

chemical features are not due to environmental factors but are the result of different genetic patterns

Although the number of different genes responsible for abnormalities in pyrrole and porphyrin metabolism is not known it is conceivable that some of the cases reported as chronic porphyria [12 13 287] mixed porphyria [39 41 286] or porphyria cutanea tarda [17 38] may be related to the type of porphyria present in the white population of South Africa. In two patients with mixed porphyria exhibiting cutaneous abdominal and neurologic manifestations liver tissue obtained by biopsy revealed high concentrations of uroporphyrin [41]. At a later date when photosensitivity was no longer present but abdominal pain was marked a repeat biopsy of the liver in one of these patients revealed little preformed porphyrin but large amounts of porphyrin precursors [41]. Moreover these patients excreted large quantities of PBG and uroporphyrin in the urine at all times. The data presently available do not permit a decision as to whether the disease of these patients is etiologically related to that in South Africa or whether it represents a separate genetic defect.

Similar difficulties are encountered in comparing the South African disease with that which Holtz and Tie [17 288] have described under the term of porphyria cutanea tarda. In their patients increased fecal excretion of coproporphyrin and protoporphyrin is a constant feature but acute attacks with outspoken neurologic manifestations are infrequent and only during such episodes are small amounts of PBG occasionally detectable in the urine. In the South African families on the other hand acute attacks involving the nervous system and at times terminating fatally occur frequently and are invariably associated with excretion of large amounts of PBG and ALA in the urine.

### *Inheritance*

The studies by Dean and Barnes [137 258] indicate that in the white population of South Africa porphyria is inherited as a Mendelian dominant trait. The 236 cases discovered occurred in 13 families all of which had a common ancestry. The disease could be traced through six successive generations.

A representative family tree is given in Fig. 30-19 [258]. The progenitor of this family was born in 1814 and had 478 descendants many of whom were still alive at the time of this study and could be traced. As seen in Table 30-7 there were 60 porphyric patients among the 125 descendants with a porphyric parent excluding children under 18 years of age in the sixth generation. In all cases only one parent had porphyria. In the second generation 5 of the 10 members had porphyria; in the third generation 16 out of 37; in the fourth generation 32 out of 59; in the fifth generation 7 out of the 19 descendants who were over 18 years of age had porphyria.

regularly contains large amounts of ALA and PBG (Table 30-5), while during remission, the excretion of these compounds may return to normal values [137]. As a rule, the occurrence of abdominal and neurologic mani-

festations appears to be associated with urinary excretion of porphyrin precursors, while increased fecal excretion of porphyrins is present at all times, apparently unrelated to the presence or absence of clinical symptoms.

#### Comparison with Other Forms of Porphyria

The high fecal excretion of coproporphyrin and protoporphyrin by white patients in South Africa clearly differentiates this form of porphyria from that studied by Waldenström in Sweden [14, 10, 137]. In the latter group of patients, fecal porphyrin excretion is either within normal limits or only moderately increased [137]. In an earlier study it had been suggested that the absence of cutaneous symptoms in Sweden and their presence in male patients in South Africa may be related to increased exposure to sunlight and to mechanical trauma [258]. In a more recent investigation, however, Dean et al. [137] found Swedish patients whose symptomatology and excretory pattern resemble those seen in South Africa, in that cutaneous symptoms are prominent and the feces contain large amounts of coproporphyrin and protoporphyrin. In South Africa, on the other hand, a group of patients of British stock who did not have South African ancestry were found to have features similar to those in the large Swedish families, in that cutaneous manifestations are absent and fecal porphyrin excretion is only slightly increased [137]. Furthermore, in Holland, these authors studied two porphyric families of which one resembles the South African cases and the other has many features of the disturbance present in the Swedish families [137]. These observations seem to indicate that the differences in clinical and bio-

In the sixth generation all descendants were under 18 years of age in a later study many of these children were found to have increased fecal porphyrin excretion [220]. Thus 48 per cent of the adults with one porphyric parent inherited the disturbance 24 males and 36 females.

Studies of the other 12 porphyric families revealed a similar pattern of inheritance. In the total group of patients 121 were male and 115 were female. Of the adults with one porphyric parent 53.4 per cent exhibited the disease. This conforms with the requirements for a Mendelian autosomal dominant type of inheritance.

#### OTHER FORMS OF FAMILIAL PORPHYRIA

Holtz and his coworkers [17] recently described a porphyric family in Britain in which 10 out of 19 members studied 4 males and 6 females exhibited abnormally high porphyrin excretion. The disturbance was

present in four successive generations. Clear evidence for autosomal dominant inheritance was established (Fig. 30-20).

The family member most severely affected was a young woman who had been subject to constipation since early childhood. At various times she experienced attacks of abdominal colic, anorexia, nausea, giddiness, postural hypotension, peripheral neuropathy, and headaches. During pregnancy her symptoms were more pronounced and bullous skin lesions appeared for the first time 1 hr after delivery. Subsequently, areolas of

**Fig 30-10** Pedigree of a family with the South African type of porphyria. The diagnosis was established on the basis of clinical manifestations and urinary analysis but fecal examinations for porphyrins have not yet been reported for this family. The last generation is comprised largely of children under 18 years of age many of whom may exhibit increased porphyrin excretion in the feces [0] (By permission of G Dean and H D Barnes [208])

relationship between urinary and biliary excretion of porphyrins [59]. In such patients during remission large amounts of coproporphyrin and protoporphyrin are excreted in the feces. On the other hand during periods of jaundice and liver failure fecal porphyrin excretion is reduced in favor of increased urinary excretion of uroporphyrin and at times of small amounts of PBG. During these latter episodes photosensitivity and abdominal colic are present and neuropathic effects may be observed. It is apparent that in the porphyric family described above [17] such a reciprocity between urinary and biliary excretion of porphyrins was not evident since urinary porphyrin excretion was either within normal limits or was only slightly increased. Furthermore none of the afflicted members exhibited jaundice or liver failure even though cutaneous abdominal and neurologic manifestations were present.

It is difficult to compare this familial form of porphyria with cases of pure porphyria cutanea tarda [18-39-41] with mixed porphyria [39-41-286] or with cutaneous porphyria in the Bantu race [42] in whom the role of genetic factors has not been clearly established. These latter patients often excrete large amounts of uroporphyrin or coproporphyrin or both in the urine and increased urinary porphyrin excretion frequently persists during periods of clinical remission [39-41]. The porphyria in the British family also differs from the hereditary porphyria in the white population of South Africa in that in the latter acute abdominal and neurologic manifestations associated with excretion of large amounts of PBG are much more prominent. Thus the available evidence suggests that the genetically controlled disturbance present in this British family may differ from both the South African and the Swedish types of porphyria and that it may be distinguished from the various cases of chronic or cutaneous porphyria in which a familial occurrence cannot be established.

Similar uncertainty in classification exists in considering other families in whom an apparently inherited abnormality in porphyrin metabolism has been observed. Tio Tiong Hoo [288] studied nine members of a Dutch family (five females four males) all of whom exhibited photodermatitis with blister formation. The first evidence of cutaneous manifestations occurred between 16 and 30 years of age abdominal and neurologic symptoms were consistently absent. Large amounts of coproporphyrin and protoporphyrin were excreted in the feces whereas the urine contained only intermittently small amounts of uroporphyrin and never contained PBG.

Calvy et al [286] reported a family of mixed porphyria in which eight members had bizarre neurologic manifestations in addition to cutaneous lesions. Finally Berger and Goldberg [292] discovered a Swiss family in which four asymptomatic members excreted large quantities of coproporphyrin in urine and stool while uroporphyrin and PBG were not detectable. The abnormality was most pronounced in a 10-year old

skin habitually exposed to sunlight exhibited marked fragility but direct light sensitivity was not detectable. Laboratory studies indicated a slight microcytic hypochromic anemia and mild impairment of hepatic function but jaundice or evidence of liver failure was not present.

Of the other 11 members who exhibited chemical evidence of porphyria only 1 was light sensitive and 11 had noticed an unusual degree of fragility of exposed skin while 3 had no cutaneous manifestations. At one time or other, however, all 9 had experienced mild gastrointestinal and

Fig. 30-20 Pedigree showing the dominant autosomal inheritance of porphyria in the family described by Holtz et al [17] (By permission of G. Holtz et al [17]).

neurologic symptoms. Chemically the characteristic finding in this family was a marked increase in fecal excretion of coproporphyrin and protoporphyrin. Elevated values were present both in patients who exhibited porphyric manifestations and in those who were in temporary remission. On the other hand urinary porphyrin excretion was within normal limits or was only slightly increased. The nature and isomer type of the porphyrins in the urine has not been reported, nor are quantitative data available on the excretion of PBG and ALA except that the semiquantitative test for PBG [142] gave at times a slightly positive reaction.

Rimington [17, 128] classifies these patients as having 'porphyria cutanea tarda' and Waldenström [16] and Rimington [289] have proposed the name protocoproporphyria hereditaria. While this latter term may be applicable to the disturbance in this particular family in that the major biochemical abnormality appears to consist in the continuous excretion of large amounts of coproporphyrin and protoporphyrin in the feces, different excretory patterns are observed in other patients with similar clinical manifestations. On the basis of study of a few isolated and apparently nonfamilial cases of porphyria which were described under the term of porphyria cutanea tarda [289, 290, 291] or of chronic porphyria [287] Rimington has postulated the existence of a reciprocal

diagnosed disease (Table 30.8). Its occurrence in more than one child of the same family and the ratio of 1:3 for affected to unaffected siblings of both sexes suggest that the abnormality is inherited as a Mendelian autosomal recessive trait. The penetrance of the abnormal gene appears to be complete since *formes frustes* are not observed. Parents and unaffected siblings of patients fail to exhibit abnormalities in porphyrin excretion.

2. Impressive progress has been made in uncovering the nature of the metabolic defect and the problem appears to be within sight of solution. The major derangement undoubtedly consists of an enzymatic defect in the developing red blood cells which leads to increased formation of porphyrins of type I isomer.

3. For the *other forms of inherited porphyria* (Table 30.8) the situation is less clear. Different genetic types can be recognized but on symptomatic grounds alone a separation is not always possible. Cases of latent porphyria or patients exhibiting only minimal symptoms are frequently encountered. Moreover in many instances the metabolic abnormality cannot be shown to be genetically controlled but may be acquired or may possibly represent a new mutation. Further studies are necessary to clarify the existing confusion.

4. In each patient or genetically homogeneous group of patients with porphyria the excretory pattern of porphyrin precursors and of porphyrins in urine and feces should be studied both during symptoms and during clinical remission. These investigations should be performed with generally accepted methods and should include as many asymptomatic blood relatives as possible. This information would provide an indispensable basis for comparison of the different clinical forms of porphyria. A most promising beginning of such a study has been made by Dean and Barnes [187]. The investigations have permitted a clear separation of the types of porphyria present in the Swedish and in the South African families. More important still is the elucidation of the nature of the metabolic defects involved and it is here that the most promising field for future studies lies.

## ADDENDUM

An additional case of congenital erythropoietic porphyria has recently been published [203]. A female infant presumably of British stock was noticed to pass pink staining meconium and urine during the first days after birth. Hemolytic anemia, splenomegaly, hypertrichosis and erythrodontia were present. Splenectomy performed at the age of 6 months resulted in marked improvement of the hemolytic process and in reduced porphyrin excretion in the urine. Erythropoietic cells in the bone marrow and peripheral blood exhibited the characteristic mor-

boy coproporphyrinuria of a lesser degree was present in both parents and in an aunt.

In all these apparently inherited disorders of pyrrole and porphyrin metabolism the number of different abnormal genes is unknown and little is understood of the nature of the metabolic defects. Moreover it is difficult to determine to what extent clinical and chemical manifestations of the inherited abnormality may be modified by superimposed acquired disturbances such as alcoholism and malnutrition or by environmental factors such as excessive exposure to sunlight. The important role of the liver as a major site of the metabolic derangement is generally recognized [16, 39, 41, 128, 132]. The association of cutaneous photosensitivity with the presence of preformed porphyrins both in the liver and in the excreta [41] is well documented. It has also been noted however that in many patients who excrete large amounts of porphyrins cutaneous manifestations may be absent or the skin may merely exhibit excessive fragility to mechanical trauma but little direct sensitivity to sunlight. The reason for this is not understood. Moreover it is not clear why in some family groups like those reported by Holtz [17] and by Calvy [286] patients may exhibit abdominal colic and neurologic disturbances in the absence of significantly increased PBG excretion. Although there is no evidence to suggest that this compound exerts a toxic effect on the gastrointestinal tract or the nervous system acute attacks are invariably associated with increased excretion of PBG and ALA in both the Swedish and the South African type of hepatic porphyria.

It has recently been suggested [132] that the appearance of preformed porphyrins in the liver and their excretion in bile and urine may reflect an inherited or acquired defect in those cellular enzyme systems which normally prevent porphyrinogens from being oxidized to porphyrins. Such a decrease in cellular reducing potential could result in increased conversion of porphyrinogens to porphyrins. Since the latter cannot be drawn back into the biosynthetic pathway (Figs. 30.8 to 30.10) they escape from the cells and are excreted. While such a mechanism would account for increased formation of preformed porphyrins in the liver it would not explain an overproduction of ALA and PBG. For instance in a patient with mixed porphyria [41] at a time of marked photosensitivity the liver exhibited a high concentration of preformed porphyrins while later when only abdominal and neurologic symptoms were present the liver contained mainly porphyrin precursors. It is possible that in such instances more than one metabolic defect is involved.

## SUMMARY

1 Among the various forms of inherited disorders of porphyrin metabolism *erythropoietic porphyria* stands out as a well defined and easily

phologic and fluorescence-microscopic abnormalities in addition needle like structures believed to consist of precipitated or crystalline porphyrins were present in some of the abnormal normoblasts and non nucleated red cells. The patient has one healthy brother.

Additional familial cases of erythropoietic porphyria have recently been published [294, 295]. According to recent reports from Turkey [296, 297] occurrence of a cutaneous form of porphyria has been observed in some 400 persons who consumed government-distributed wheat contaminated with various fungicides. Preliminary information indicates that the wheat contained hexachlorobenzene and several organic mercury and copper compounds.

A syndrome of cachexia, photosensitivity, bullous skin eruptions, hyperpigmentation and hypertrichosis developed in individuals who had consumed contaminated wheat 1 month to 3 years prior to the onset of manifestations. Urine and feces contained large amounts of uro- and coproporphyrins but increased excretion of urinary porphobilinogen was not observed. Abdominal and neurologic manifestations were absent but there was functional and anatomic evidence of liver disease.

The syndrome appeared to be more frequent in children under 15 years of age but was also found in adults of various racial background who had been exposed to contaminated cereals.

The preliminary reports suggest that this syndrome may represent an acquired form of porphyrinuria and may perhaps be similar to the porphyrinuria seen in the Bantus of South Africa.

## Chapter 31

### Hereditary Spherocytosis

---

*James H. Jandl*

In hereditary spherocytosis a hemolytic process is associated with an intrinsic defect in the metabolism and structure of the red cell. The cardinal features of this disease are (1) spherocytosis (2) increased rate of red cell turnover (3) splenomegaly (4) familial occurrence and (5) almost invariably benefit from splenectomy. There are many synonyms for this hemolytic disease the most common of which are congenital hemolytic anemia and congenital hemolytic jaundice.

#### *Incidence*

Although not restricted to any single race hereditary spherocytosis is most frequent in people of European origin. Among those of Northern European descent it is the most prevalent of the hereditary hemolytic disorders. This disease affects the sexes equally and often is manifest in early infancy [1, 2].

#### *Clinical Description*

The major symptoms arise from anemic hypoxia. The severity of the anemia varies from time to time and from patient to patient. As the result of increased red cell destruction a mild degree of acholuric jaundice is usually present although it may be variable or intermittent and tends to be less pronounced in early childhood [2]. Gall tones of the pigment type are common even in childhood [3] and presumably are precipitated from bile containing high concentrations of bilirubin. The spleen is usually palpable but the liver is usually normal in size. Although less frequent than in sickle-cell anemia chronic leg ulcers occasionally develop particularly in adulthood. The ulcers are usually bilateral just above the malleoli and ordinarily disappear after splenectomy. A wide assortment of skeletal abnormalities has been described in patients with hereditary spherocytosis. Some of these are presumably caused by the expanding

morphologically from those appearing in acquired anemias manifesting spherocytosis such as hemolytic anemias caused by 'autoantibodies' or by certain oxidant drugs. In hereditary spherocytosis the red cell mean corpuscular volume is usually in the normal or low normal range while the hemoglobin concentration (MCHC) tends to be above normal. The reverse is usually true of the red cells in acquired hemolytic anemia with spherocytosis. The red cell in hereditary spherocytosis is therefore deficient in surface area [7].

Fig 31-1. Comparison of osmotic fragility curve of normal red cells and of hereditary spherocytes. These are summation curves depicting the portion of red cells hemolyzed at various concentrations of sodium chloride; they represent average values as determined by Emerson and his associates [10]. As indicated by the continuous lines (freely drawn) hereditary spherocytes are on the average slightly more susceptible to hypotonic lysis than normal red cells, and a small portion of these cells is striking in this respect, as indicated by a leftward tail in the osmotic fragility curve. After 24 hr of sterile incubation at 37°C (interrupted line) hereditary spherocytes increase their thickness to diameter ratio more rapidly than do normal red cells, as indicated by the greater leftward shift in the osmotic fragility curve.

Spherocytes are identified by microscopic examination of peripheral blood smears or suspensions in which they appear as dark rounded cells lacking a central pale area and smaller in diameter and greater in thickness than normal red cells. Spheroidicity may be measured in terms of osmotic fragility. In the osmotic fragility test red cells are suspended in aqueous solutions containing various concentrations of sodium chloride. Since there is almost no electrolyte exchange during the relatively short duration of the test, osmotic equilibrium is achieved by the movement of water across the red cell membrane. In hypotonic solution the red cell swells until it approaches a sphere. Any further uptake of water abruptly

force of the hyperplastic erythroid bone marrow during the formative years

### *Pathology*

As in other chronic hemolytic disorders there are compensatory normoblastic hyperplasia of the bone marrow and extension of the red marrow into the mid shafts of the long bones. Occasionally extramedullary erythropoiesis may appear with formation of paravertebral masses. The spleen as observed at operation is darkly congested with blood and usually weighs from 500 to 2 000 gm although a precise weight is often difficult to establish because of a continuing leakage of blood. On section of the spleen the sinuses are often observed to be dilated and empty whereas the pulp cords are congested with red cells. The significance of this finding is uncertain since recent studies [4] of ultrathin sections of the normal spleen indicate that the splenic sinuses and the splenic cords are merely different functional phases of the same anatomic structure.

### *Laboratory Findings*

The presenting laboratory findings are those common to all chronic hemolytic processes: anemia, an increased concentration of reticulocytes, an increased concentration of indirect reacting (largely nonglucuronide) bilirubin in the serum, and an increased rate of fecal urobilinogen excretion. There is little or no hemoglobin in the plasma. The hemoglobin which is released from destroyed red cells is catabolized to bilirubin at the site of destruction (so called extravascular hemolysis).

The severity of the manifestations of the disease depends upon the rate of red cell destruction which may range from slightly to greatly increased and the rate of compensatory red cell production by the marrow. The erythropoietic response to anemia in this disease is unusually brisk. Accordingly the anemia may be minimal despite moderately rapid rates of red cell destruction. Patients having only slight anemia with disproportionately severe icterus and reticulocytosis are said to have a "compensated form" of hemolytic anemia [5]. On the other hand the equilibrium between the rates of red cell destruction and production may be dramatically upset by episodes of bone marrow failure (aplastic crises) during which erythroid hypoplasia and reticulocytopenia may ensue [6]. Most commonly such episodes are precipitated by infections. These infections may be otherwise mild but if highly communicable may cause an epidemic of aplastic crises in an afflicted family.

### *The Spherocyte*

The characteristic feature of this type of hereditary hemolytic anemia is the spherocyte (more accurately a cell more nearly spheroidal than the normal red cell). The red cells in hereditary spherocytosis may differ

Fig 31-1 Influence of the spleen on the osmotic fragility of hereditary spherocytes. The majority of the red cells were only slightly more spherical than normal. However 10 per cent of the red cells in the peripheral blood (continuous line) represent an apparently separate population which distributes around a maximum increment of osmotic lysis at a sodium chloride concentration of between 0.55 and 0.60 gm per cent. A similar but proportionately larger population of spherical cells was found simultaneously emerging from the splenic vein (dotted line) in the splenic pulp itself (interrupted line). The highly spherical population of red cells constituted a majority of those present. Observations such as this indicate that hereditary spherocytes trapped in the spleen undergo further spherical transformation much as they do on incubation *in vitro* (Fig 31-1).

underlying the spherical shape and the abnormal susceptibility to injury by erythrostatics.

## BIOCHEMICAL ABNORMALITIES OF HEREDITARY SPHEROCYTOSIS

### FUNCTION OF THE NORMAL RED CELL

Although the immature red cell is uniquely concerned with the synthesis of hemoglobin, it is otherwise comparable in its metabolic activity to many other tissue cells. When it matures to an adult red cell shortly after its release into the circulation, its function becomes primarily that of transporting oxyhemoglobin. This function requires the preservation

renders the cell membrane porous causing leakage of intracellular contents including hemoglobin. Accordingly assuming that the cells have a normal internal osmolarity and providing the pH is kept constant the osmotic fragility test is a precise measure of how nearly spherical a cell is at the time of exposure to a hypotonic medium [8]. Under conditions of this test the red cells including the newly formed reticulocytes [9] of patients with hereditary spherocytosis usually manifest an increase in osmotic fragility. Thus spheroidicity is attained at higher concentrations of sodium chloride than is the case with normal red cells (Fig. 31.1).

## MECHANISM OF RED CELL DESTRUCTION

### *Red Cell Survival*

Hereditary spherocytes have a diminished life span in the patient or in the normal subject when the spleen is present but their survival is almost normal in the splenectomized patient or normal subject [10]. Normal red cells survive normally when transfused into patients with hereditary spherocytosis [11]. Thus the red cell defect is intrinsic, is nontransferrable and causes destruction of the cell only in the presence of the spleen.

### *Role of the Spleen*

Although spherocytosis persists after splenectomy the excessive destruction of the spherocyte ceases. The following observations have shown that the spleen is the actual and sole site of abnormal red cell destruction and does not simply exert an intermediate influence: (1) The spleens of patients are characteristically engorged with blood and the bilirubin content of splenic vein blood considerably exceeds that of the peripheral blood [12]. (2) Hereditary spherocytes labeled with  $\text{Cr}^{51}$  and reinjected into patients or into normal subjects are sequestered in the spleen but not elsewhere [13, 14] and prior to actual sequestration their circulation time through the spleen is abnormally slow [15].

Direct observations of splenic blood in hereditary spherocytosis have shown that the red cells in the splenic pulp are more nearly spherical than those in the peripheral circulation [16-19] (Fig. 31.2). Spherocytes are selectively retained in the pulp of spleens as determined after transfusion *in vivo* [16-20] and after splenic perfusion *in vitro* [18]. Indeed it has recently been shown [21] that spherocytes can be separated from normal red cells simply by passage through mechanical (Millipore) filters *in vitro*. These observations support in all essential details the hypothesis of Ham and Castle [22, 23] that hereditary spherocytes are trapped in the spleen by virtue of their increased thickness. There they are subject to hemoconcentration [24] and erythrostasis and undergo metabolic changes to which they are peculiarly susceptible leading to their destruction. In recent years efforts have been made to identify the biochemical lesion

Fig 31.2 Influence of the spleen on the osmotic fragility of hereditary spherocytes. The majority of the red cells were only slightly more spherical than normal. However, 10 per cent of the red cells in the peripheral blood (continuous line) represent an apparently separate population which distributes around a maximum increment of osmotic lysis at a sodium chloride concentration of between 0.55 and 0.60 gm per cent. A similar but proportionately larger population of spherical cells was found simultaneously emerging from the splenic vein (dotted line) in the splenic pulp itself (interrupted line); the highly spherical population of red cells constituted a majority of those present. Observations such as this indicate that hereditary spherocytes trapped in the spleen undergo further spherical transformation, much as they do on incubation *in vitro* (Fig. 31.1).

underlying the spherical shape and the abnormal susceptibility to injury by erythrostasis.

## BIOCHEMICAL ABNORMALITIES OF HEREDITARY SPHEROCYTOSIS

### FUNCTION OF THE NORMAL RED CELL

Although the immature red cell is uniquely concerned with the synthesis of hemoglobin, it is otherwise comparable in its metabolic activity to many other tissue cells. When it matures to an adult red cell shortly after its release into the circulation, its function becomes primarily that of transporting oxyhemoglobin. This function requires the preservation

renders the cell membrane porous causing leakage of intracellular contents including hemoglobin. Accordingly assuming that the cells have a normal internal osmolarity and providing the pH is kept constant the osmotic fragility test is a precise measure of how nearly spherical a cell is at the time of exposure to a hypotonic medium [8]. Under conditions of this test the red cells including the newly formed reticulocytes [9] of patients with hereditary spherocytosis usually manifest an increase in osmotic fragility. Thus spheroidicity is attained at higher concentrations of sodium chloride than is the case with normal red cells (Fig. 31.1).

## MECHANISM OF RED CELL DESTRUCTION

### *Red Cell Survival*

Hereditary spherocytes have a diminished life span in the patient or in the normal subject when the spleen is present but their survival is almost normal in the splenectomized patient or normal subject [10]. Normal red cells survive normally when transfused into patients with hereditary spherocytosis [11]. Thus the red cell defect is intrinsic, is nontransferrable and causes destruction of the cell only in the presence of the spleen.

### *Role of the Spleen*

Although spherocytosis persists after splenectomy the excessive destruction of the spherocyte ceases. The following observations have shown that the spleen is the actual and sole site of abnormal red cell destruction and does not simply exert an intermediate influence. (1) The spleens of patients are characteristically engorged with blood and the bilirubin content of splenic vein blood considerably exceeds that of the peripheral blood [12]. (2) Hereditary spherocytes labeled with  $\text{Cr}^{51}$  and reinjected into patients or into normal subjects are sequestered in the spleen but not elsewhere [13-14] and prior to actual sequestration their circulation time through the spleen is abnormally slow [15].

Direct observations of splenic blood in hereditary spherocytosis have shown that the red cells in the splenic pulp are more nearly spherical than those in the peripheral circulation [16-19] (Fig. 31.2). Spherocytes are selectively retained in the pulp of spleens as determined after transfusion *in vivo* [16-20] and after splenic perfusion *in vitro* [18]. Indeed it has recently been shown [21] that spherocytes can be separated from normal red cells simply by passage through mechanical (Millipore) filters *in vitro*. The observations support in all essential details the hypothesis of Ham and Castle [22-23] that hereditary spherocytes are trapped in the spleen by virtue of their increased thickness. There they are subject to hemoconcentration [24] and erythrostasis and undergo metabolic changes to which they are peculiarly susceptible leading to their destruction. In recent years efforts have been made to identify the biochemical lesion

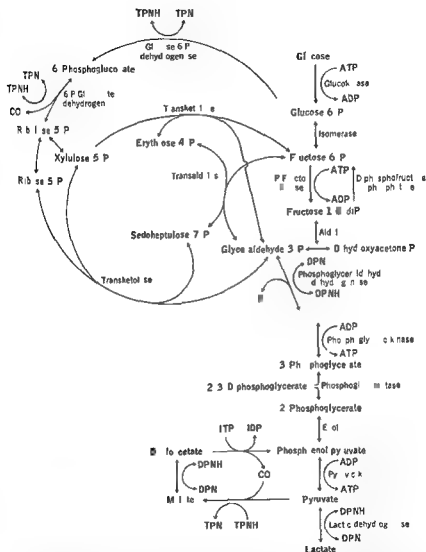

Fig 31.3 Metabolism of glucose by red cells. The main pathway in red cells is the anaerobic (Embden-Meyerhof) pathway portrayed vertically in this scheme. For every mole of glucose consumed in this chain of reactions 4 moles of ATP and 2 moles of inorganic phosphate are utilized; in return 4 moles of ATP are generated and 2 moles of lactate are lost. The cyclc pathway at the upper left represents the hexose monophosphate shunt (pentose phosphate pathway) which serves the important function of generating TPNH.

of (1) hemoglobin molecules and (2) the physical integrity of the cell. The preservation of hemoglobin depends to a large extent upon intracellular reducing mechanisms and involves the formation of reduced triphosphopyridine nucleotide (TPNH). The metabolism of TPNH in the red cell is discussed in Chap. 32. The metabolic activities necessary for the physical preservation of the cell are known to include the generation of high energy phosphate compounds. It is in this respect that hereditary spherocytes appear to be defective.

#### PRESERVATION OF THE PHYSICAL STRUCTURE OF RED CELLS

The survival of the red cell in the circulation is critically dependent upon the preservation of smooth biconcave shape and upon maintenance of individual free suspensibility. In its repetitive passage through the filtering systems of the body of which the spleen is the most exacting, slight alterations in the thickness of the red cell or in the stickiness of its surface lead to sequestration and eventual destruction of the cell.

The supporting structure of the red cell resides in the outer portion of the cell membrane and consists of a membrane [26] or a network [26] of lipoprotein. The protein component, a large complex fibrillar protein termed *elmin* [26], is insoluble and is probably metabolically inactive [27]. The lipid components bound to this insoluble structural protein diffuse from red cells especially under nonphysiologic conditions [28] and exchange rapidly with plasma lipids [29]. Some lipids may be actively synthesized by red cells [30], although this activity is very limited and probably occurs only in the youngest circulating cells [31]. The actual processes which induce and maintain the biconcave structure of the red cell membrane are unknown.

The volume and thickness of red cells depend upon ion transport across the cell membrane. Since distribution of the anions chloride and bicarbonate appears to be passive, maintenance of red cell volume depends largely on the distribution of cations. The movement of cations across this membrane involves energy dependent processes in which potassium is actively concentrated in the cell and sodium is actively discharged. Both ions are in a state of continuous flux [32-35]. The energy for ion transport is derived from glucose metabolism [32-35].

#### METABOLISM OF THE NORMAL RED CELL

##### *Glycolysis*

Energy for the functions of the adult red cell is derived entirely from the metabolism of glucose. Unlike immature red cells including reticulocytes [36], the mature red cell lacks cytochromes and many of the components of the tricarboxylic acid cycle. Since the red cell thus has little ability to utilize oxygen or to metabolize lactic acid, glucose is mainly catabolized

fragility (Fig 31 1) [16 19 22] Swelling is accompanied by a decrease in electrolyte gradients permitting an influx of sodium and a lesser efflux of potassium [32 45] The net gain in electrolytes and water which results may reflect in part that sodium transport is more active than potassium transport [32-35] Indeed after 48 hr of incubation when the intracellular and extracellular concentrations of the cations have both approached equilibrium the red cells return to their original volume [45] However the mechanism of red cell swelling during incubation *in vitro* is still incompletely understood Swelling occurs to about the same extent when the cells are incubated in a potassium rich buffer as in a sodium rich buffer [46] Swelling is presumably due chiefly to oncotic pressure although an increase in intracellular osmolarity [47] may be contributory

During the first several hours red cell osmotic swelling is largely prevented by glucose unless glucose utilization is blocked by the addition of fluoride [32] Red cell swelling caused by prolonged storage is only partially inhibited by glucose and is attended by a depletion of cellular 2,3-diphosphoglycerate [42] and of ATP [48] and the appearance of free purines [49] The changes can be partially reversed by certain ribosides [50] particularly inosine [51] which are cleaved by purine nucleoside phosphorylase [42 52] possibly at the red cell membrane releasing ribose 1 phosphate [53] This ester through its conversion to ribose 5-phosphate presumably could be metabolized to triose phosphate by way of the hexose monophosphate shunt [50] (Fig 31 3) At least some purines may enter the erythrocyte there is recent evidence that adenine itself may also be utilized for ATP synthesis by intact rabbit red cells [54]

## METABOLISM OF HEREDITARY SPHEROCYTES

### *Abnormalities of Ion Transport*

The hemoglobin concentration in hereditary spherocytes frequently exceeds the upper limits of normal Although the exact explanation for this is lacking it is generally attributed to defective electrolyte regulation within the cell Potassium and water content are diminished [55] Although the sodium concentration is normal [46] the rate of sodium turnover is high [56 57]

An even more striking and consistent finding is the crucial observation that these cells are abnormally susceptible to erythrostasis When hereditary spherocytes are incubated at 37 C they become spheroidal even more rapidly than do normal red cells [17] (Fig 31 1) Indeed since the cells are usually partially spherical prior to incubation their exaggerated rate of increase of spheroidicity during *stasis* renders the measurement of osmotic fragility after incubation for 24 hr the most sensitive single test for detecting hereditary spherocytosis [17-19] This exaggerated increase

by the glycolytic (Embden Meyerhof) pathway (Fig. 21.3) and lactate accumulates. In addition to this pathway the mature red cell contains all the enzymatic components of an alternative oxidative pathway, the hexose monophosphate shunt [77] (pentose phosphate pathway of *alv* Chap. 3). This pathway cycles glucose 6-phosphate through several intermediate steps, the first two of which are oxidation in which FPN serves as hydrogen acceptor. Reduced FPN is involved in a number of processes important to the red cell including the reduction of methemoglobin and of oxidized glutathione. When the shunt is active for every three glucose molecules which take the pathway three molecules of carbon dioxide are released and two molecules of fructose 6-phosphate and one molecule of triose phosphate are formed [78]. Ordinarily this pathway is probably little utilized in red cells as indicated by the negligible oxidation of glucose to carbon dioxide *in vitro*. When substances such as methylene blue and other permeable and reversibly reducible dyes which may diffuse into the red cell are added this oxidative shunt is activated to full capacity and cellular respiration is increased dramatically [79, 80]. Such substances substitute for the otherwise deficient mechanism for carrying electron directly from FPNH to oxygen. Possible utilization of the hexose monophosphate shunt *in vivo* has not been quantitated but it is undoubtedly far less active than the anaerobic pathway.

Since the red cell is known to possess only a limited store of glycogen metabolic activity directly depends upon the availability of glucose in the surrounding medium. At physiologic plasma levels glucose can be rapidly transported across the cell membrane so as to maintain equal glucose levels in plasma water and cell water [41]. This transport does not require insulin [41].

### Phosphate Metabolism

Phosphate for participation in red cell metabolism is obtained principally from the orthophosphate of plasma by direct incorporation into glyceraldehyde 3-phosphate probably in the red cell membrane [52, 67]. The phosphorylated triose (1,3-diphosphoglycerate) acts as a phosphate donor in generating adenosine triphosphate (ATP); the more stable diester 2,6-diphosphoglycerate which has a uniquely high concentration in the red cell acts as a phosphate depot. In this respect the diphosphoglycerate occupies a strategic position in red cell energy metabolism comparable to that of creatine phosphate in muscle cells [55].

### Effects of Isotonicity

When normal red cells are incubated *in vitro* under sterile conditions, they undergo progressive structural and chemical changes. During the first 24 hr the cell swell and accordingly show an increase in osmotic

the cell membrane or is merely accentuated by the generally increased rate of intracellular phosphate turnover

### *Effect of Splenectomy*

Although the exact nature of the biochemical defect in hereditary spherocytosis is not known it is apparent that the defect is not merely a consequence of a metabolic change induced by the spleen for the metabolic abnormalities of the spherocytes are not influenced by splenectomy [60]. The failure of splenectomy to affect the abnormal phosphate turnover of hereditary spherocytes does not disprove the possibility that this abnormality is in part acquired in the circulation. The contribution of the spleen to the overall metabolism of the circulating red cells would be difficult to predict and may well be neutralized by the simultaneously opposing factors of (1) increased metabolic stress from splenic erythrostaia (2) the selection of a population of red cells having increased metabolic resistance by virtue of the filtration of spherocytes and (3) the accelerated release of young red cells from the marrow. There remains the possibility that a still more fundamental metabolic error exists in these cells and that phosphate metabolism is only secondarily affected.

## GENETIC ASPECTS

The defect of hereditary spherocytosis is probably inherited as a Mendelian dominant characteristic. This interpretation was first based on surveys which depended upon overt clinical and hematologic manifestations for identification of the defect [64-66] and has been confirmed in studies utilizing more precise laboratory criteria [1, 67]. If the disease is inherited as a Mendelian dominant trait one parent and half the siblings and offspring should be affected. Although abnormal red cells are usually detectable in one parent of each proband a number of instances have been reported in which the red cells of both parents were normal to existing tests [1, 64, 66, 67]. In two large series of patients there has emerged a significant deficit of affected siblings but no deficiency in the expected proportion of affected offspring [1, 66].

There are several possible explanations for the deficit of affected relatives. (1) expression of the disease is highly variable [67] and may be conditioned by such environmental factors as the spleen; there may well be some patients with red cell abnormalities of a mildness undetectable by the osmotic fragility method after incubation of the blood just as there are some with red cell abnormalities undetectable by this method without incubation. (2) some cases may be a result of gene mutation a possibility which would explain the higher incidence in offspring than in siblings and parents. (3) the deficiency in affected siblings may be partly a result of the unusually high rates of miscarriage and infant mortality.

in spheroidicity during erythrostasis is not associated (at least initially) with an abnormal uptake of sodium and water from the surrounding plasma

Since the energy for ion transport depends upon glycolytic mechanisms attention has been focused upon the glucose metabolism of the hereditary spherocyte. The abnormal degree of autohemolysis which ensues when hereditary spherocytes are incubated at 37°C for more than 48 hr can be largely prevented by the addition of glucose [45]. Fluoride nullifies this effect of glucose [48]. As with normal red cells the swelling of hereditary spherocytes exposed to the metabolic stress of erythrostasis is largely prevented by glucose or adenosine and related nucleosides [49].

#### *Abnormalities of Phosphate Metabolism*

The over all rates of glucose consumption [45] and of phosphate exchange [50] in hereditary spherocytes were found to be normal. However the observations of Franker, Altman and Young [50] revealed a consistent abnormality in the intracellular distribution of phosphate. When hereditary spherocytes were incubated in plasma containing  $P^{32}$  labeled orthophosphate there was a disproportionately small recovery of  $P^{32}$  from the intracellular and stromal phosphate esters and a proportionately greater recovery of  $P^{32}$  from the inorganic phosphate pool of the cell. In the red cells of over half the patients studied these workers [50] also found that the addition of adenosine during incubation of hereditary spherocytes with  $P^{32}$  increased toward normal the portion of  $P^{32}$  which could be recovered from phosphate esters. Since Franker et al. interpreted the cellular concentrations of ATP, ADP, 2,3 diphosphoglycerate and inorganic phosphate to be normal they attributed the abnormal distribution of  $P^{32}$  to a diminished rate of turnover of intracellular organic phosphate rather than to changes in the sizes of the respective phosphate pools [50]. Inorganic and ester phosphate levels in the hereditary spherocytosis cell by more recent calculations [51] may be larger than those originally presented [50]. Thus it appears that the movement of phosphate into the various intermediates deviates from normal but the exact nature of this abnormality is presently unclear.

A specific enzymatic defect in hereditary spherocytes has not been described. The finding that the uptake and retention of phosphate by hereditary spherocytes is impaired by a concentration of sodium fluoride ( $10^{-3} M$ ) which has little or no effect upon normal red cells [52] suggests the possibility that  $Mg^{++}$  activated enzymes are involved. One of these enzymes, adenosine triphosphatase, has been found to be normally active in hereditary spherocytes [53] thus abnormalities of both enolase [52] and a phosphokinase [53] have been proposed by exclusion. It is equally possible that the sensitivity of hereditary spherocytes to fluoride poisoning is a function of the structure, permeability, or enzyme placement in

#### 4 One hypothesis which can be proposed is as follows

a An abnormality in intermediary carbohydrate metabolism in hereditary spherocytes renders them peculiarly dependent upon the level of glucose and other metabolites in their environment. Consequently when hereditary spherocytes are separated from a continuous supply of glucose containing plasma as in erythrostasis an abnormally rapid depletion of high energy phosphate compounds occurs ion transport breaks down and the cells increase in spheroidicity at an abnormally rapid rate. This conditioning of the red cells by repetitive passage through the spleen over a period of approximately 10 days [70] creates a minor population of osmotically very fragile thickened red cells.

b With the resulting increase in its thickness the hereditary spherocyte is unable to pass at a normal rate through the splenic sinuses and is thereby subjected to further erythrostasis and erythrocytic concentration which deprive it of metabolic substrate. Being abnormally susceptible to such deprivation the cell becomes even more spheroidal is unable to escape from the spleen and eventually is destroyed by dissolution of the cell membrane.

5 An alternative hypothesis is that structural organization alone may be responsible for the changes found in hereditary spherocytosis and that this abnormality of surface may account for the trapping tendency in the spleen.

6 Hereditary spherocytosis therefore represents an inherited disease of the red cell. The energy requirements of the red cell are relatively so low and its physical deformity of so little consequence in the general circulation that this metabolic defect would be harmless but for the exceptional capacity of the spleen to filter out abnormal cells and to subject them to stasis.

It has not yet been possible to design experiments which will choose between these alternatives

A number of reports have described the association of hereditary spherocytosis with a variety of constitutional or skeletal defects including tower skull, polydactyly, arched palate, eye abnormalities and ovarian hypofunction [5, 68, 69]. It is not certain, however, that the reported incidence exceeds that of the general population. There is apparently no genetic linkage between hereditary spherocytosis and such inherited constitutional features as sex, blood group, eye color or ear form [60].

There is no definite example of homozygous hereditary spherocytosis although it has been suspected in a family of 13 children, all with hereditary spherocytosis, 9 of whom manifested physical or mental retardation [60]. Race [66] reported a mating of first cousins, both of whom had hereditary spherocytosis. Three of the children were affected, one was normal, and there were two miscarriages.

An interesting observation which emerged from the metabolic studies of hereditary spherocytes was that at least one abnormality observed in hereditary spherocytosis has a familial pattern. It was reported that the defect in intracellular partition of  $P^{32}$  could be largely corrected by adenosine in cells from 10 of 18 patients investigated [60]. In this respect all afflicted members of each family behaved uniformly, regardless of the severity of the anemia [60]. The biochemical basis for this effect of adenosine is unknown, but it cannot be ascribed simply to a deficit in purine nucleoside phosphorylase [60]. This apparent genetic subdivision of patients with hereditary spherocytosis may reflect the existence of two (or more) basic disease entities manifesting in common an inherited spherocytosis.

## SUMMARY

1 Hereditary spherocytosis is a congenital hemolytic anemia caused by an intrinsic defect in the metabolism of the red cell which is transmitted as a Mendelian dominant characteristic.

2 The exact nature of this defect is unknown. It is manifested by the formation in the bone marrow of red cells which are deficient in surface and which thereby approach a spherical rather than a normal discoidal form. This deformity is associated with an abnormality in the metabolism of high energy phosphate compounds by the red cell. Whether this metabolic abnormality is primary or simply secondary to an alteration of the structural organization of the cell membrane is as yet uncertain.

3 Since unlike most body cells, red cells lack intrinsic mechanisms for the direct utilization of oxygen and depend almost entirely on an aerobic glycolysis for the generation of energy, there is rapid depletion of the energy sources necessary for ion transport and for maintenance of cell structure under erythrostatic conditions.

## Chapter 32

### Drug induced Hemolytic Anemia (Primaquine Sensitivity)

---

*Ernest Beutler*

Over the years those charged with the care of the sick have often been dismayed to find that a drug that was innocuous to many patients produced catastrophic results in a few. In 1953 it first became possible to study in detail one such drug sensitivity reaction, the hemolytic effect of the 8-aminoquinoline antimalarial primaquine (Fig. 32-1). These studies not only helped to clarify the mechanism of sensitivity to this drug but also led to the demonstration that a hereditary biochemical lesion of the erythrocyte was responsible for many other drug-induced hemolytic anemias and for favism. Because primaquine sensitivity is the prototype of this kind of hemolytic reaction, only the history of 8-aminoquinoline hemolytic anemia will be reviewed. That of related drug sensitivities is similar.

The history of the 8-aminoquinoline compounds resembles that of many drugs: the compound was hailed as causing no harm to the blood when it was first introduced in 1926; scarcely a year later severe, even fatal, hemolytic anemias were reported. The first 8-aminoquinoline introduced to clinical medicine was plasmoquin (pamaquine) (Fig. 32-1) which was used by Mühlens [1] to treat syphilitic patients who had been inoculated with malaria.

Following Cordes [2] initial report of hemolytic anemia associated with the administration of this drug, many similar reports appeared from all over the world [3-35]. Typically the patient developed dark, often black, urine a few days after primaquine therapy was begun. Jaundice was noted, and the red blood count and hemoglobin were found to be markedly diminished. Usually the patient recovered, but sometimes he succumbed to massive destruction of red blood cells.

Attempts have been made to implicate immune mechanisms in the

compounds. The clear cut demonstration by Dern et al [38] that sensitivity to the hemolytic anemia induced by these drugs was a property of the red blood cells made it possible to focus attention on the central problem the abnormality of the erythrocyte. These studies demonstrated beyond doubt the important facts that hemolysis is limited to the older members of the red cell population [39] and that red cells sensitive to primaquine are sensitive also to a large number of other compounds [40].

Studies of the biochemistry of primaquine sensitive cells suggested that their sensitivity to hemolysis was related in some way to their glutathione (GSH) content [41] and the stability of their GSH [42]. Examination of the pathways of GSH metabolism in drug sensitive red cells by Carson et al [43] disclosed the probable primary defect a deficiency of the enzyme glucose 6-phosphate dehydrogenase. Subsequent observations established unequivocally that patients with favism have the same red cell defect as primaquine-sensitive subjects [44-56]. Hemolytic anemia has been elicited in a subject with known sensitivity to fava beans by administration of primaquine [57]. In addition it was found that red cells undergoing hemolysis following exposure of individuals to a wide variety of agents had the same biochemical defect as had been described in primaquine-sensitive red cells (Table 32.1).

TABLE 32.1 COMPOUNDS KNOWN TO HAVE INDUCED HEMOLYSIS OF PRIMAQUINE SENSITIVE RED CELLS

## HEMATOLOGY OF DRUG INDUCED HEMOLYTIC REACTIONS

### CLINICAL COURSE

#### *Result of Drug Administration to a Sensitive Individual*

The clinical course of primaquine induced hemolysis has been studied under carefully controlled conditions by Dern et al [69]. When a drug sensitive person is given 30 mg primaquine daily there is little or no

etiology of hemolytic anemia. A nonspecific hemagglutinin was described in the blood of one patient [21], but it was demonstrated [33] subsequently that autoagglutinins could be found in the blood of patients receiving pamaquine who did not develop hemolytic anemia. Skin testing was attempted [27]. Fragility studies [11, 29, 33, 34] and Donath Landsteiner tests [19, 25] were carried out. In addition, *in vitro* studies were made of hemolysis induced by pamaquine and related compounds or by the plasma

Fig 32 1 Structural formulas of representative types of drugs which cause hemolytic anemia in primaquine sensitive subjects

of patients who had recently received pamaquine [29-30]. None of these studies solved the problem of why some persons develop acute hemolytic anemia when given pamaquine and others do not.

A few observations have been made which in retrospect were much more significant. The appearance of Heinz bodies in the red cells of a patient with mild hemolytic anemia occurring during pamaquine therapy was noted in 1928 [8]. Attention was called to the familial nature of pamaquine sensitivity and analogies were drawn between this disorder and favism [31]. The difference in susceptibility of different races to hemolysis by pamaquine was recognized [18, 22, 25, 27, 29, 33].

It was not until after the introduction of primaquine (Fig 32 1) a therapeutically more effective 8-aminoquinoline [37] that it became possible to study intensively the hemolytic anemia induced by the e

*Hemolytic Anemia in Nonsensitive Individuals*

Volunteer subjects have given an essentially all or none response to daily administration of 30 mg primaquine. On the other hand large doses of those drugs which induce hemolysis in sensitive subjects may induce milder hemolysis in nonsensitive subjects. The hemolytic effect of phenylhydrazine is well known. In addition it has been demonstrated that acetanilid 3.6 gm daily or primaquine 120 mg daily will induce mild hemolysis in a normal person. On the other hand some persons have taken 120 or even 240 mg primaquine daily without any evidence of hemolysis. A combination of 90 mg primaquine and 3.6 gm acetanilid daily produced severe hemolysis in a normal subject [40]. Para amino salicylic acid-induced hemolytic anemia has been described in a subject with nonsensitive red cells as judged by the GSH stability test and assay for glucose 6 phosphate dehydrogenase (see below) [70].

The hemolytic anemia caused by Guadin has an immunologic basis [70]. This drug induced hemolysis may arise by entirely different mechanisms in patients who are not primaquine sensitive.

DRUG SENSITIVITY AS AN INTRINSIC ABNORMALITY OF  
THE ERYTHROCYTE

Dern et al [38] transfused chromium 51 labeled red cells from a sensitive subject into nonsensitive recipients. The survival of the transfused cells was normal until primaquine was administered to the nonsensitive recipient. Rapid destruction of the  $\text{Cr}^{51}$  labeled red cells then occurred. The converse experiment was also carried out. Chromium 51 labeled red cells from a normal individual were transfused into a known primaquine sensitive subject. In contrast to the results obtained in the first experiment primaquine administration had no effect on the survival of the  $\text{Cr}^{51}$  labeled cells from the normal donor although the primaquine-sensitive recipient underwent a typical acute hemolytic episode.

EFFECT OF CELL AGE ON HEMOLYSIS

A curious aspect of primaquine hemolytic anemia is that even if drug administration is continued during a hemolytic episode hemolysis will cease spontaneously. When  $\text{Cr}^{51}$  labeled red cells from a sensitive individual who had become tolerant to primaquine were transfused into a subject who had never previously received primaquine the labeled cells were unaffected when primaquine was given. Red cells from the sensitive subject were no longer susceptible to destruction. When a primaquine-sensitive individual who was no longer destroying his own red cells although still receiving primaquine was given a transfusion of  $\text{Cr}^{51}$

evidence of hemolysis during the first 2 or 3 days. In contrast to immunologic sensitivity, subsequent administration of drug does not shorten this latent period. After 30 mg has been administered daily for 2 or 3 days the urine begins to turn dark. In mild cases the patient may observe no other abnormality. In more severe cases the patient complains of weakness and abdominal and back pain and develops icterus and black urine. Heinz bodies appear in many of the red cells [70]; the hemoglobin, red blood cell and hematocrit values fall rapidly and the number of reticulocytes rises. This 'acute hemolytic phase' ends spontaneously in about 1 week, even when drug administration is continued, and the 'recovery phase' begins. The patient feels better, the color of the urine becomes normal and the hemoglobin, red cell and hematocrit values begin to rise. The reticulocyte count remains high at first and then declines. Throughout this time the Coombs test result is negative and red cell fragility remains unaltered. The only morphologic changes in the blood are polychromasia and the appearance of Heinz bodies in the red cells. Finally, the peripheral blood picture returns to normal and the symptoms vanish, even though administration of the drug is continued in the same dosage that initially caused hemolysis.

Acetanilid and sulfanilamide [69] have also been given under controlled laboratory conditions to subjects known to be drug sensitive. In addition, there are many reports of hemolytic anemia induced accidentally by naphthalene [64, 68-67, 71], nitrofurantoin (Furadantin) [61, 72] and fava beans [47, 73] in persons who were demonstrated to be sensitive or who on clinical grounds may be presumed to have been sensitive. Thus hemolytic anemia induced by acetanilid, sulfanilamide, Furadantin or naphthalene is similar to that induced by primaquine. The self-limited nature of the hemolytic anemia has not been demonstrated, however, with the latter two compounds. Naphthalene-induced hemolytic anemia may at times be considerably more explosive than that observed with primaquine administration.

Fava bean-induced hemolysis may occur within hours of contact with fava beans and is often more severe than primaquine-induced hemolysis. Some factor other than the red cell defect of primaquine sensitivity is required for the production of fava bean-induced hemolysis; in every case of favism in which the red cells have been studied, the erythrocytic defect of primaquine sensitivity has been demonstrated, but subjects known to have the latter defect have eaten fava beans with impunity [47, 74].

Hemolysis induced by thiazol-sulfone may vary greatly in intensity. Careful studies of the mechanism of this variability suggest that it is due to differences in absorption or metabolism of the drug [69]. In addition, Cr<sup>51</sup>-labeled primaquine-sensitive red cells are not necessarily destroyed *in vivo* when fava beans are fed [74a].

## GSH METABOLISM AND ASSOCIATED PATHWAYS IN THE NORMAL ERYTHROCYTE

### OVERALL METABOLISM OF THE ERYTHROCYTE

Several reviews of the metabolism of the mature mammalian erythrocyte have been published in the past decade [78-79]. The metabolism of the erythrocyte which is exceedingly complex may be considered in complete when compared with that of most other cells. For example the mature red cell is unable to synthesize protein but does appear to

Fig. 1. Glucose metabolism in the red blood cell. Abbreviated scheme based on various sources [8-79]. The site of the metabolic block in primary drug-sensitive erythrocytes is indicated by the double line between glucose-6-phosphate and 6-phosphogluconate.

synthesize certain simpler compounds such as glutathione [80-82], nicotinamide mononucleotide and diphosphopyridine nucleotide [82a, 82b]. While it was at one time believed that fat synthesis took place in erythrocytes [83-84], more recent studies indicate that lipid synthesis occurs only in reticulocytes and white cells [84a, 84b]. The red cell requires a source of energy for synthetic processes for the maintenance of ion concentration gradients and for the reduction of methemoglobin which is being formed continuously. The chief source of energy of the red cell

labeled red cells from another primaquine-sensitive subject the transfused cells were destroyed rapidly the sensitive individual retained an undiminished capacity to destroy sensitive cells in his circulation Thus it was demonstrated that the refractory state which develops in primaquine-sensitive individuals is due not to altered metabolism of the drug after prolonged administration, but rather to an alteration in reactivity of the red cell population [69]

It was postulated that the red cell population might consist of a mixture of sensitive and nonsensitive red cells and that sensitivity might be a function of red cell age This hypothesis was confirmed by labeling the red cells of a sensitive subject with  $\text{Fe}^{59}$  By bleeding the subject before administration of the radioisotope and by blocking reutilization with nonlabeled saccharated iron oxide administered intravenously it was possible to confine labeling to red cells of a relatively narrow age range Primaquine was administered when the tagged red cells were 8 to 21 days of age and again when the tagged cells were 63 to 76 days of age Destruction of labeled cells occurred only during the second course of drug administration even though the patient experienced an acute hemolytic episode during both courses of drug administration [39]

#### STUDIES OF DRUG SENSITIVE ERYTHROCYTES BY ROUTINE HEMATOLOGIC TECHNIQUES

The abnormal response of the primaquine-sensitive subject is not another manifestation of a previously described red cell abnormality Coombs tests have been carried out [38 70] The Ham acid hemolyis test has been performed [70] Osmotic and mechanical fragility has been determined [70] Sickle-cell tests have been performed [58 70 77] and the electrophoretic mobility of the hemoglobin has been determined on paper at pH 8.6 [70] The percentages of alkali resistant hemoglobin [70] and methemoglobin [38 58 70] in the red cells have been measured These tests have failed to disclose any relationship between the defect of primaquine sensitivity and other intrinsic red cell abnormalities

Other studies have sought to determine how primaquine-sensitive red cells differ *in vitro* from normal red cells Lysis of primaquine-sensitive cells by primaquine pamaquine 6-methoxyquinoline quinoline and aniline was compared with lysis of normal red cells by the same compounds [70] The accelerating effects of primaquine on saponin hemolysis and of naphthalene on taurocholate hemolysis were measured [70] The effect of prolonged incubation with primaquine on osmotic mechanical and chemical fragility was observed [70] None of these studies showed any difference between primaquine sensitive and primaquine insensitive erythrocytes

### *Reduction of Methemoglobin*

TPNH is utilized for the reduction of methemoglobin through the methemoglobin reductase system [97] in the presence of methylene blue. The available evidence would suggest that this is probably not a physiologically important system [87]. The concept that impairment of TPNH reduction is not important in maintaining normal methemoglobin levels is supported by the finding that primaquine-sensitive cells in the presence of glucose and without methylene blue reduce methemoglobin at a normal rate [65] and by the fact that primaquine-sensitive individuals do not develop greater degrees of methemoglobinemia than normal subjects [33, 58].

### *Synthetic Processes*

TPNH may play an important role in a variety of reductive synthetic processes [98-99]. While some of these probably do not occur in erythrocytes, others may. It may well be that here lies the most important role of TPNH in maintaining erythrocyte integrity.

## GSII METABOLISM

Reduced glutathione (GSII) is a tripeptide of glutamic acid, cysteine, and glycine. It has one free sulfhydryl ( $-SH$ ) group. Recent reviews of the reactions of GSII may be consulted for more detailed description of its chemistry [100-101].

### *Biosynthesis*

Isotopically labeled glycine is incorporated into the glutathione of mature mammalian erythrocytes [80-81]. The finding that all three amino acids are labeled and that the distribution of radioactivity among them remains constant suggests that complete biosynthesis of GSII takes place rather than mere exchange or partial synthesis within the red cell [82].

### *Oxidation*

GSII undergoes oxidation to the disulfide form (GSSG) under a variety of conditions.

In pure solution GSII is relatively stable. In the presence of traces of heme [102], metallic ion, particularly copper [102], and selenite [103], it rapidly undergoes autooxidation to the disulfide form. GSII may be oxidized by hemoglobin peroxide through the mediation of glutathione peroxidase [93]. It appears likely that it can serve as a hydrogen donor

comes from the breakdown of glucose but in vitro inosine may be utilized as well (Fig 32 2)

### *Anaerobic Metabolism*

Under physiologic conditions glucose metabolism in the red cell is primarily anaerobic and yields lactic acid. The derived energy is stored in the form of high energy phosphate bonds by phosphorylation of adenosine diphosphate (ADP) to form adenosine triphosphate (ATP). During glycolysis 1 mole of diphosphopyridine nucleotide (DPN) is reduced in the oxidation of glyceraldehyde 3 phosphate to 1 3 diphosphoglyceric acid and 1 mole of reduced DPN is oxidized in the reduction of pyruvic to lactic acid.

### *Oxidation of Glucose—the Hexose Monophosphate (HMP) Pathway*

An alternate pathway of glucose metabolism is also available. This is the hexose monophosphate shunt (see Chaps 3, 4 and 31) in which glucose undergoes oxidative catabolism. Under normal conditions the HMP pathway accounts for only a small proportion of the glucose utilized by the red blood cell. Methylene blue and certain other dyes readily activate this route of metabolism by linking it to molecular oxygen and to methemoglobin [86-87]. Glucose is phosphorylated at the 6 position and then undergoes oxidation to 6 phosphogluconic acid through the action of glucose 6 phosphate dehydrogenase. In this step 1 mole of triphosphopyridine nucleotide (TPN) is reduced. Phosphogluconic acid then undergoes oxidation presumably forming 6 phospho 3 keto gluconate. Again 1 mole of TPN is reduced. The normal fate of the ribose 5 phosphate formed is less well understood. Various cleavages and condensations may take place [88-89].

### PATHWAYS OF OXIDATION OF TPNH IN THE ERYTHROCYTE

Several alternate routes of oxidation of reduced TPN (TPNH) are available in the red cell. Presumably these reflect some of the physiologic roles of TPNH and of the TPNH generating system in the red cell.

### *Reduction of Oxidized Glutathione (GSSG)*

TPNH is oxidized in the course of enzymatic reduction of oxidized glutathione [90, 91]

It has been suggested that a normal route of electron transfer from TPNH may involve the  $\text{GSSG} \rightleftharpoons \text{GSH}$  reaction [92]. This might occur through oxidation of GSH by peroxide compounds [93-94]. GSH is readily converted to GSSG in vivo. In red cells GSH disappears relatively rapidly when red cells are exposed to oxygen in the absence of glucose [95, 96].

vent the accumulation of peroxide hemoglobin complexes and thereby reduce choleglobin and methemoglobin formation in intact red cells which have been poisoned with azide [94] Yet it is not established that these are physiologic roles

Red cells poisoned with sulfhydryl reagents such as *p* chloromercuribenzoate hemolyze rapidly in vitro [118 119] Such experiments yield no reliable information regarding the need for GSH in the cell since these agents are nonselective in their inactivation of —SH groups It is also known that as the GSH of oxygenated shed blood decreases spontaneous hemolysis is accelerated [90] Since other changes also undoubtedly take place when blood is oxygenated in the absence of glucose the falling GSH and spontaneous hemolysis cannot be considered as having unequivocally a cause and effect relationship

GSH serves as coenzyme for glyoxalase known to be present in red cells [120] but no function is known for glyoxalase in the erythrocyte

It may be as suggested by Barron [121] for other tissues that GSH helps to maintain —SH groups in the reduced state It is of interest that glucose 6-phosphate dehydrogenase [122] and GSH reductase [118 119] both of which serve to keep GSH in the reduced state are inhibited by sulfhydryl reagents Unlikely though it seems it may be that GSH plays no obligatory role in the economy of the red cells Further work utilizing new approaches will be necessary to elucidate the physiologic role of this compound in the red cell

## BIOCHEMISTRY OF DRUG SENSITIVE ERYTHROCYTES

### ABNORMALITIES FOUND INDEPENDENTLY OF DRUG ADMINISTRATION

#### *Glucose 6 Phosphate Dehydrogenase Activity Deficiency*

Dilute hemolyzates from drug sensitive erythrocytes are unable to promote reduction of GSSG normally when glucose 6-phosphate is the substrate Normal GSSG reduction takes place when TPNH or 6-phosphogluconate is supplied This is the basic observation in defining at the enzymatic level the difference between drug sensitive and non-sensitive erythrocytes [43] It indicates that the red cells of sensitive subjects are deficient in glucose 6-phosphate dehydrogenase activity This has been confirmed by many investigators using both the GSH linked assay procedure [50] and an assay method that measures directly the reduction of TPN by hemolyzates supplied with glucose 6-phosphate as substrate [46 51 54 5, 65] Mixtures of various proportions of normal and sensitive hemolyzates do not reveal any enzyme inhibition [122a] The enzyme deficiency seems to be particularly severe in older red cells [123 123a] By using the GSSG linked assay system it has been shown that incubation with a nondialyzable stromal factor present in both sensitive and non

for the reduction of methemoglobin [93, 94, 104] while undergoing oxidation to GSSG. It is apparently oxidized rapidly when red cells are oxygenated [95, 96]. In some tissues GSH may be oxidized by dehydroascorbic acid [105].

### *Reduction*

GSSG may be reduced to GSH nonenzymatically by a variety of agents, including zinc [106], sodium amalgam [107], cysteine [108] and hydrogen sulfide [109] and may also be readily reduced electrolytically [110]. A glutathione reductase [90] which mediates the reduction of the disulfide form with TPNH as the hydrogen donor, has been found in several rat tissues [90, 111] and a number of plant tissues [90, 112]. DPN is ineffective as coenzyme [90, 113].

Human red cells also contain a substance which catalyzes the reduction of GSSG with TPNH serving as a hydrogen donor [91, 114]. Reduced DPN will also serve as a hydrogen donor [91, 114] in the case of red cell GSH reductase although somewhat less efficiently. The relative efficiency of DPNH and TPNH as hydrogen donors has not been found to change in over one thousand fold purification with respect to protein concentration of the red cell enzymes [115]. The degree of specificity of red cell glutathione reductase has not been studied. It is not identical with methemoglobin reductase. Purified preparations of the latter do not promote TPNH oxidation in the presence of GSSG [115]. GSSG reductase can be inhibited with *p*-chloromercuribenzoate without inhibiting methemoglobin reductase [115]. It is entirely possible that glutathione reductase represents the combined activity of several enzymes, and that some of these may be involved also in methemoglobin reduction. This problem deserves further study.

### *Catabolism*

Aside from the interconversion of GSH and GSSG, other pathways for the metabolism of red cell glutathione apparently exist at least in abnormal circumstances. Thus when red cells are incubated with acetyl phenylhydrazine in the absence of glucose, there is a decrease not only in GSH but also (after an initial increase) in GSSG [116, 117]. Since the analytical technique used in these determinations also measures cystine or cysteine, it seems unlikely that some method of breakdown other than simple hydrolysis of the peptide bonds is involved. It has also been suggested that GSSG is destroyed in ordinary hemolyzates [94].

### *Function in the Economy of the Cell*

The function of GSH in the red cell must be regarded as unknown. As has been pointed out, GSH can serve as a hydrogen donor in the reduction of methemoglobin in hemolyzates [93, 94, 104]. It also can pre-

vent the accumulation of peroxide hemoglobin complexes and thereby reduce choleglobin and methemoglobin formation in intact red cells which have been poisoned with azide [94] Yet it is not established that these are physiologic roles

Red cells poisoned with sulfhydryl reagents such as *p* chloromercuribenzoate hemolyze rapidly in vitro [118-119] Such experiments yield no reliable information regarding the need for GSH in the cell since these agents are nonselective in their inactivation of —SH groups It is also known that as the GSH of oxygenated shed blood decreases spontaneous hemolysis is accelerated [95] Since other changes also undoubtedly take place when blood is oxygenated in the absence of glucose the falling GSH and spontaneous hemolysis cannot be considered as having unequivocally a cause-and-effect relationship

GSH serves as coenzyme for glyoxalase known to be present in red cells [120] but no function is known for glyoxalase in the erythrocyte

It may be as suggested by Barron [121] for other tissues that GSH helps to maintain —SH groups in the reduced state It is of interest that glucose 6-phosphate dehydrogenase [122] and GSH reductase [118-119] both of which serve to keep GSH in the reduced state are inhibited by sulfhydryl reagents Unlikely though it seems it may be that GSH plays no obligatory role in the economy of the red cells Further work utilizing new approaches will be necessary to elucidate the physiologic role of this compound in the red cell

## BIOCHEMISTRY OF DRUG SENSITIVE ERYTHROCYTES

### ABNORMALITIES FOUND INDEPENDENTLY OF DRUG ADMINISTRATION

#### *Glucose 6 Phosphate Dehydrogenase Activity Deficiency*

Dilute hemolyzates from drug sensitive erythrocytes are unable to promote reduction of GSSG normally when glucose 6 phosphate is the substrate Normal GSSG reduction takes place when TPNH or 6-phosphogluconate is supplied This is the basic observation in defining at the enzymatic level the difference between drug sensitive and nonsensitive erythrocytes [48] It indicates that the red cells of sensitive subjects are deficient in glucose 6-phosphate dehydrogenase activity This has been confirmed by many investigators using both the GSH linked assay procedure [50] and an assay method that measures directly the reduction of TPN by hemolyzates supplied with glucose 6-phosphate as substrate [46-51-54-55-56] Mixtures of various proportions of normal and sensitive hemolyzates do not reveal any enzyme inhibition [122a] The enzyme deficiency seems to be particularly severe in older red cells [123-123a] By using the GSSG linked assay system it has been shown that incubation with a nondialyzable stromal factor present in both sensitive and non

sensitive cells results in loss of enzymatic activity from sensitive cells from at least some subjects but not from nonsensitive cells [50 124] A stromal factor, therefore appears to inactivate the enzyme in the drug sensitive cells but not in the nonsensitive cells The pH optimum of crude enzyme from normal and sensitive cells has been reported to differ [122a] However this observation has not been confirmed when more highly purified enzyme has been studied [125] Thus the apparent deficiency of the enzyme may in fact be due to an abnormal enzyme molecule which has lower activity and is especially susceptible to damage [122a 126], but much further work needs to be done to determine whether this is the case

There is considerable variability in the severity of enzyme deficiency observed in various subjects In addition recent studies have shown that there is a marked difference between the erythrocyte glucose 6 phosphate dehydrogenase levels of Negro and Caucasian subjects with this enzymatic deficiency The defect is much more severe in affected Caucasian subjects [126a]

Enzyme assays have also been carried out on the leukocytes platelets and liver tissues of sensitive subjects The leukocyte glucose 6-phosphate dehydrogenase activity of Negro subjects with red cell glucose 6-phosphate dehydrogenase deficiency is only slightly reduced and the statistical significance of the reduction is borderline [126a] In the case of Caucasian subjects however a well marked reduction of glucose 6 phosphate dehydrogenase activity was observed in the leukocytes of affected individuals [126b] Reduced platelet enzyme levels have been found in sensitive Caucasian subjects [126b] A borderline decrease in liver enzyme activity in affected subjects has been reported [126c]

#### *Effects of Glucose 6 Phosphate Dehydrogenase Deficiency*

**GSH Deficiency** Red cells from drug sensitive individuals are deficient in GSH and also in total glutathione (GSH + GSSG) [127 128] The GSH deficiency was demonstrated originally in primaquine sensitive subjects both by GSH assay with a nitroprusside method of relatively low specificity and by the use of the more specific alloxan 300 technique [41] Because almost all the nonprotein sulfhydryl of the red cell is GSH [129] the results obtained by means of these two methods were almost identical both yielding low values in drug sensitive and normal values in nonsensitive individuals The deficiency of red cell GSH in drug sensitive individuals is fairly consistent especially if the determinations on several days are averaged [41] There is some overlap of individual values [42] Low GSH values have also been observed in erythrocytes of subjects with hemolytic anemia due to fava beans or drugs other than primaquine [44 45 53 55] It has been claimed that the GSSG as well as the GSH of sensitive erythrocytes is decreased [123] This finding

has been disputed because of the relatively nonspecific assay method for GSSG which was employed [127]

**GSH Instability** There is rapid destruction of GSH [116] when red cells from a sensitive or non sensitive individual are suspended in a saline-phosphate buffer and incubated with acetylphenylhydrazine. Concurrently there is an increase in the red cell GSSG level. Subsequently the GSSG falls slightly, so that a significant decline in total glutathione takes place during the course of the experiment [117]. If glucose or inosine

Fig 3-3 The effect of incubation at 37°C with phenylhydrazine, primaquine and ascorbic acid on the GSH levels of sensitive and non-sensitive red cells [130]

is added to the system the non-sensitive red cells protect their GSH completely but protection of GSH in sensitive cells is incomplete [116, 130]. The same effect can be demonstrated also with other reducing agents e.g. primaquine, phenylhydrazine, ascorbic acid (Fig 32-3) [48, 130], Furadantin [61],  $\alpha$  and  $\beta$  naphthoquinone [63] and certain Vitamin K derivatives [63, 67]. Substrates other than glucose and inosine including ribose, lactate, pyruvate, malate and fumarate have little or no protective properties [116]. The addition of methylene blue does not enhance the effectiveness of glucose in protecting red cell GSH [116].

The mechanism by which acetylphenylhydrazine destroys GSH in red cells *in vitro* has been investigated in some detail. Oxygenation of the red cells is required for the destruction of GSH. Carbon dioxide and CO are extremely effective in protecting the GSH of sensitive cells from destruction [116] (Fig 32-4). Acetylphenylhydrazine modifies oxyhemoglobin in such a way that it rapidly oxidizes GSH [116]. The nature

of the intermediate compound has not been determined but it may be that a hemo<sub>2</sub>lobin peroxide compound is formed and that GSH destruction is mediated by GSH peroxidase [94]. It appears, therefore, that acetylphenylhydrazine induces a change in hemoglobin which causes it to oxidize rapidly the GSH of red cells. Normal red cells have the capacity to reduce TPN by oxidizing glucose and to reduce the GSSG to GSH. Normal cells deprived of glucose and cells lacking glucose 6 phosphate

Fig 32-4 The effect of oxygen, carbon dioxide, and carbon monoxide on the GSH content of drug-sensitive red cells incubated with acetylphenylhydrazine. Carbon monoxide and carbon dioxide exerted a pronounced protective effect. (From E. Beutler [48] by permission of the *Journal of Laboratory and Clinical Medicine*.)

dehydrogenase do not reduce enough TPN to maintain GSH in the reduced state. Apparently GSSG is destroyed as it accumulates within the red cell.

An additional complication is that certain hemolytic compounds inhibit purified glucose 6-phosphate dehydrogenase [131]. It remains to be seen what role this may play in bringing about GSH instability in intact red blood cells.

**CO<sub>2</sub> Production and O<sub>2</sub> Consumption** Since the hexose monophosphate shunt is the only known pathway of oxygen consumption and CO<sub>2</sub> production in the red cell [86], an enzyme deficiency along this route would be expected to decrease O<sub>2</sub> consumption and CO<sub>2</sub> production. This is indeed the case when O<sub>2</sub> consumption and CO<sub>2</sub> production of drug-sensitive red cells incubated in the presence of methylene blue are

compared with those of normal cells [123] As expected the amount of  $\text{CO}_2$  produced from the 1 position of labeled glucose was less in drug sensitive than in control cells [123] Furthermore comparison of the utilization of the 1 carbon and the 6-carbon of labeled glucose administered intravenously to drug sensitive and normal subjects has revealed marked retardation of utilization of the 1 carbon by drug sensitive subjects [132] This finding would imply that glucose 6-phosphate dehydrogenase deficiency is not limited to the red cells of sensitive subjects (see below)

**Methemoglobin Reduction** Reduction of methemoglobin in the presence of methylene blue a TPNH linked process is diminished in drug sensitive cells [60]

**TPN/TPNH Ratio** The ratio of TPN to TPNH is increased in sensitive cells [133-135] as might be predicted with a defect in the TPN reducing system A slight increase in the  $\text{DPN}/\text{DPNH}$  ratio has also been described [135]

**Compensatory Mechanisms** A number of other enzymatic changes have also been observed in primaquine sensitive red cells independently of drug administration Increased activity of red cell GSH reductase [92] aldolase [50 134 136] glyceraldehyde phosphate dehydrogenase [55] and lactic dehydrogenase [55] has been reported Activity of the last three enzymes has also been reported to be normal [123 134 136a] Some of these increased activities may represent compensatory changes which enable the red cell to live out a normal life span when not challenged by a hemolytic drug [136]

#### OTHER BIOCHEMICAL MEASUREMENTS IN SENSITIVE RED CELLS

The activity of phosphogluconic dehydrogenase [74] phosphohexose isomerase [74] purine nucleoside phosphorylase [74] triose isomerase [114] 3 phosphoglycerate kinase [134] pyruvate kinase [134] isocitric dehydrogenase [136a] and malic dehydrogenase [136] has also been measured in drug sensitive red cells and has been normal Enolase activity was normal in one subject but decreased in another [134] Chromatography of the amino acid residues of hydrolyzed hemoglobin from sensitive red cells demonstrated no abnormality [48] It has been claimed that a decrease in ADP and AMI as measured by enzymatic hydrolysis occurs in the whole blood of affected subjects [134] Using the more exact chromatographic technique of Bartlett [137] the author and coworker [110] have been unable to confirm this observation (see below) It has also been claimed that intracellular  $\text{K}^+$  of affected cells is significantly diminished [134] No abnormality has been detected in total lipid fractions [134]

Chromatography of phosphorylated intermediary metabolites of the red cells of a drug sensitive individual has been carried out on Dowex 1

TABLE 32.2 RED CELL PHOSPHORYLATED INTERMEDIATES AS SEPARATED CHROMATOGRAPHICALLY ON A DOWEN 1 COLUMN

resin [115] employing the techniques developed by Bartlett [137]. The results (Table 32.2) reveal an increase in hexose monophosphate and diphosphate which may readily be explained on the basis of a metabolic block in the direct oxidation of hexose monophosphate. No other abnormalities were observed.

#### CHANGES OCCURRING IN ERYTHROCYTES DURING DRUG ADMINISTRATION

##### *Glucose 6 Phosphate Dehydrogenase*

Only the older members of a red cell population are destroyed when primaquine is administered to a sensitive subject [39]. Studies based on age fractionated red cells indicate that higher levels of glucose 6-phosphate dehydrogenase are present in young cells than in old cells [133-140] and that this disparity exists also when red cells from primaquine sensitive subjects are examined [123, 123a, 126a]. Since a deficiency of glucose 6-phosphate dehydrogenase appears to be the basic defect of primaquine sensitive cells, it would be most attractive to suppose that the higher levels of this enzyme in younger cells protect them against destruction and that the lower levels found in older members of the red cell population render them particularly sensitive to destruction.

Dawson et al. [65] have reported near normal glucose 6-phosphate dehydrogenase levels in subjects with naphthalene-induced hemolytic anemia and Sansone et al. [141] have found normal levels and Grignani and Brunetti [141a] near normal levels in subjects with falcic crises. On the other hand, while measurements of glucose 6-phosphate dehydrogenase activity during the administration of primaquine to sensitive subjects show a slight rise concurrently with the reticulocytosis which follows hemolysis, enzyme activity soon returns to predrug administration levels according to Flanagan et al. [127]. This happens even though the subject is no longer sensitive to the hemolytic action of primaquine. The latter observation is based on the GSH linked assay system and would seem to preclude the attractive explanation that the younger red cells of a drug sensitive individual owe their resistance to hemolysis to higher glucose 6-phosphate dehydrogenase activity and is difficult to reconcile with the findings on *in vitro* age-separated cells [123, 123a, 126a, 133-140]. The discrepancy in these results may be the result of the different assay methods.

##### *GSH*

The administration of primaquine to a drug-sensitive subject results in a rapid fall in the average GSH level of the red cell. This fall precedes the major portion of red cell destruction. There is then a return of average red cell GSH to the same or slightly higher level than prior to drug ex-

hibition [127] Similar observations have been made in subjects with favaism [49 53, 55, 56] and sulfonamide induced [49] hemolytic anemia. It has been suggested that initially GSH in the older red cells is destroyed and that GSH depleted cells are then removed from the circulation [116]

The fate of GSH in sensitive red cells challenged in vivo by drug requires further study. No increase in red cell GSSG has been observed concurrently with GSH destruction in vivo even though many observations have been made at frequent intervals. This has been interpreted as indicating that the route of GSH destruction in vivo does not involve conversion to GSSG [127]. This seems unwarranted, however, since it is entirely possible that the steady state condition of the red cell does not permit GSSG accumulation and that rapid degradation of GSSG takes place as it is formed. It has been reported that the results of the GSH stability test (see below) are not affected by primaquine administration [127]. However transient glutathione instability in red cells of sensitive subjects has been reported following naphthalene [66] and fava bean-induced hemolysis [49 55 141]

### *Methemoglobin Formation*

The formation of methemoglobin in sensitive subjects given drug is not greater than that observed in nonsensitive subjects [33 68] and may even be less [60]

### *Mechanism of Red Cell Destruction*

While much has been learned of the biochemical abnormalities of drug sensitive red cells and of the changes which occur during drug administration comparatively little is known of how these changes lead to red cell destruction when a potentially hemolytic drug is administered.

Hemolytic drugs do not produce preferential lysis of drug sensitive red cells in vitro [70]. Hence they must modify the red cell in such a way that it is selected for destruction presumably by the reticuloendothelial system. While normally the spleen may play a predominant role in the destruction of red cells it has been found that even a splenectomized subject rapidly destroyed drug sensitive red cells transfused into him when drug was administered [38].

Heinz bodies which appear in the red cells at the onset of the hemolytic episode and which disappear as hemolysis progresses may represent a microscopically visible manifestation of the biochemical insult sustained by sensitive cells when drug is administered [70]. The production of Heinz bodies can be reproduced in vitro it is enhanced by sulfhydryl reagents such as arsenite and iodoacetate. Oxygen is required for their formation [142]. Since they are believed to consist of particles of denatured protein [143] it is possible that the insult is one of protein

denaturation occurring under oxidative conditions and that sulfhydryl compounds play a defensive role

Red cell GSH is low in sensitive individuals and falls sharply under conditions of both *in vivo* [127] and *in vitro* [42] exposure to a drug. For this reason this compound has received much attention in attempts at outlining the course of events leading to the destruction of drug sensitive red cells. The suspicion that GSH is involved in this reaction is supported by the disappearance of GSH from cells just prior to their destruction [127] and by the fact that sulfhydryl reagents promote Heinz body formation *in vitro* [142]. Nonetheless sulfhydryl reagents inhibit many enzymatic reactions within red blood cells and it is entirely possible that other more important but less easily measured changes which take place concurrently with GSH destruction may be the primary events leading to red cell destruction. Caution must be taken not to interpret the easily measured GSH changes as being necessarily important in determining destruction of the red cell. As pointed out in an earlier section the role of GSH in the red cell must be regarded as unknown.

### METHODS OF DETECTION OF DRUG SENSITIVE ERYTHROCYTES

The *in vivo* challenge of erythrocytes with a drug is obviously an impractical means of studying the incidence or genetics of drug sensitivity. For such studies it is necessary to depend on *in vitro* means for detection of drug sensitive persons. Several methods for distinguishing apparently normal red cells of drug sensitive subjects from those of normal persons are now available.

#### HEINZ BODIES

When drug sensitive erythrocytes are incubated with a variety of reducing agents such as acetylphenylhydrazine, phenylhydrazine, primaquine or ascorbic acid a different pattern of Heinz body formation is observed than occurs when normal cells are incubated under identical conditions [142]. This forms the basis of a method by which fairly reliable differentiation of sensitive from non sensitive subjects can be made [15, 61, 67, 141, 142]. The chief advantage of this technique is the simplicity with which the test can be performed on large numbers of blood samples. It is also the only method by which positive results are consistently obtained even when the patient is undergoing a hemolytic crisis [127, 141]. Disadvantages include the sensitivity of the test to changes in oxygen tension and to change in the hematocrit [142]. It is not surprising therefore that false positive results have been reported on subjects with thalassemia [141]. Less easily explained are false positive results observed in nonanemic subjects [142].

**Procedure [142]** A buffered acetylphenylhydrazine solution is prepared by dissolving 100 mg acetylphenylhydrazine in 100 ml of a 1/15 phosphate buffer pH 7.6 containing 200 mg glucose per 100 ml. Whole gently agitated venous blood 0.1 ml is added with a 'blow-out' pipet to 2 ml of the acetylphenylhydrazine solution in a test tube with an inner diameter of 12 mm. The suspension is mixed immediately and aerated two or three times by drawing approximately 0.1 ml of the suspension into a pipet and blowing it and a small quantity of air back into the suspension. Incubation is carried out in a 37°C water bath and the mixing procedure is repeated after 2 hr. After 4 hr a small droplet of the suspension is placed on a cover slip which is then inverted on a microscope slide that contains a droplet of half saturated crystal violet in 0.73 per cent NaCl solution. An area in which the structure of the red cells is well preserved is selected for microscopic examination. One hundred cells are examined and are classified as containing either five (or more) or four (or less) Heinz bodies. With rare exceptions over 40 per cent of red cells from sensitive subjects contain five or more Heinz bodies. Less than 30 per cent of red cells from nonanemic non-sensitive subjects contain this many Heinz bodies. Before the blood of anemic patients is to be examined it is useful to centrifuge it slowly and to remove sufficient plasma to adjust the hematocrit to 40 per cent [127].

#### GSH LEVELS

There is a highly significant difference between the average GSH level of sensitive and nonsensitive red cells [41]. Some investigators initially attempted to use this measurement as a means for identifying sensitive subjects [44, 48, 144]. Unfortunately there is too much overlap between the GSH levels of normal and sensitive red cells to make this a useful technique for the detection of drug sensitivity [42].

#### GSH STABILITY TEST

The incubation of red cells with acetylphenylhydrazine and measurement of GSH stability is a useful method for the detection of the red cell defect of drug sensitivity [42, 150]. This test is somewhat more time consuming than the Heinz body method but can be performed relatively simply and rapidly. It is considerably less sensitive to changes in oxygen tension and hematocrit than is the Heinz body procedure. It gives clear separation of sensitive from nonsensitive subjects. A recent report [142] suggests that this procedure is not reliable in detecting females who are sensitive to the *in vivo* hemolytic effects of primaquine but correlation between glucose 6-phosphate dehydrogenase assays and glutathione stability tests has been excellent in the hands of most investigators [51, 54, 55, 141]. Only a few discrepancies between GSH stability tests and enzyme assays have been reported [50, 55, 146]. The author regards this as the method of choice for survey and other routine purposes.

Considerable confusion was caused originally by the observation that red cells obtained from infants up to 75 hr of age had unstable GSH [54, 63, 146-148]. Zinkham [146] has clearly demonstrated that this is

stability is due to rapid depletion of already diminished quantities of blood glucose. Addition of glucose to the system reverses the apparent defect in all but a few infants who prove to have glucose 6 phosphate dehydrogenase deficiency and may therefore be regarded as truly sensitive [146-149].

**Procedure** [42] Venous blood is drawn into heparin or into ACD<sup>1</sup> solution. The use of the latter anticoagulant assures the presence of sufficient glucose

Fig 375 The results of the GSH stability test as carried out on the blood of seven non-sensitive and five sensitive male subjects (E B Utter [1] by permission of the Journal of Laboratory and Clinical Medicine)

■ substrate for GSH reduction. If ACD solution is used acceptable results may be expected even if sterile samples are stored for 4 weeks at 4°C [54-150]. One milliliter of blood is added to a tube containing 5 mg acetyl phenylhydrazine. These are mixed and shaken to ensure thorough oxygenation and incubated for 3 hr at 37°C. At the end of the incubation period 2 ml distilled water is added. Within a few minutes 5 ml of 3 per cent glacial metaphosphoric acid (35 per cent  $\text{H}_2\text{O}_2$ ) is added with agitation followed by approximately 1 gm NaCl and the mixture is shaken. Two milliliters of a filtrate is added to 6 ml of a saturated  $\text{NaCl}$  solution in a 25-mm cuvette with all solutions equilibrated at 20 to 22°C. One milliliter of 2 per cent sodium nitroprusside and 1 ml of a  $\text{NaCN}$  (0.67 M)– $\text{Na}_2\text{CO}_3$  (1.5 M) solution are added to develop color. A spectrophotometer reading is made at 520 mμ within 1 min.

After incubation with acetylphenylhydrazine the red cell GSH of sensitive subjects is usually less than 20 mg per 100 ml. Non-sensitive red cells usually

One liter contains 16 gm sodium citrate, 4.8 gm citric acid, 29.5 gm glucose. One milliliter of ACD is used per 5 ml whole blood.

contain more than 35 mg GSH per 100 ml red cells (Fig 32 5) In most cases the difference in color is sufficient to permit correct interpretation with the naked eye [47] This test is unaffected by a wide variety of disease conditions [60 64]

#### GLUCOSE 6-PHOSPHATE DEHYDROGENASE ASSAY

Demonstration of decreased activity of glucose 6-phosphate dehydrogenase is probably the most reliable and exact means for the detection of drug sensitive red cells It should be recalled that 6-phosphogluconate formed in the assays which have been used will be oxidized further if 6-phosphogluconic dehydrogenase is present This results in the reduction of additional TPN Unless a great excess of phosphogluconic dehydrogenase is present, and this does not appear to be true in red blood cells [150] the amount of TPN reduced will depend upon the level of both phosphogluconic dehydrogenase and glucose 6 phosphate dehydrogenase It must be remembered, therefore that abnormalities in the level of phosphogluconic dehydrogenase can also influence the results in GSSG linked TPN linked and dye-linked assays for glucose 6-phosphate dehydrogenase The latter enzyme is apparently quite stable when red cells are stored in ACD solution No decline in enzymatic activity has been noted in 4 weeks [151] The validity of results obtained on a single sample of red cells which showed a sudden drop in enzymatic activity on the seventh day of storage [140] is to be doubted

#### *GSH linked Assay*

An assay for red cell glucose 6-phosphate dehydrogenase has been described in which the reduction of GSSG to GSH is measured by determining the amount of reduced glutathione in the mixture at various intervals after beginning incubation Glucose 6-phosphate dehydrogenase and glutathione reductase are supplied in the hemolyzate The former is the limiting factor in the reaction

**Procedure [43]** Red cells are washed in saline solution and hemolyzed in 5 vol distilled water for 1 hr at 4 C The hemolyzate is centrifuged at 1400 g for 90 min (maximum temperature 37 C) The cleared hemolyzate is dialyzed for 12 hr at 4 C against 40 vol 0.067 M phosphate buffer pH 7.4 Incubation is carried out at 22 C in a 14-ml reaction mixture buffered to pH 7.4 by 0.036 M tris (hydroxymethylaminomethane) Oxidized glutathione is added to give a final concentration of  $1 \times 10^{-4}$  M TPN  $1 \times 10^{-4}$  M glucose 6-phosphate  $5 \times 10^{-4}$  M and dialyzed hemolyzate 0.5 to 0.0 ml final volume to 14 ml with distilled water The reaction is stopped at the end of 15 min by the addition of metaphosphoric acid and reduced glutathione concentration is determined A modification [92] of this procedure has been described in which the hemolyzate is prepared in the cold The concentration of some of the reactants has been altered and the reaction is carried out at 37 C

### *Spectrophotometric Measurement of the Reduction of TPN*

A more rapid method for the measurement of glucose 6 phosphate dehydrogenase activity in red cells is an adaptation of the procedure described earlier for the determination of this enzyme in other tissues [152]. It is based on the spectrophotometric measurement of the appearance of TPNH in a reaction mixture consisting of glucose 6-phosphate, Tris buffer solution and hemolyzate (Fig. 32.6).

Fig. 32.6. Replicate direct spectrophotometric assays of glucose 6-phosphate dehydrogenase carried out on the red cells of one normal (—) and one sensitive (---) subject. The assay method used was as described by Mark except that 0.5 ml 0.05 M glucose 6-phosphate was added as substrate instead of 0.5 M and that the total volume was increased to 3 ml. Hemoglobin concentration in the two cuvettes was nearly the same. It is apparent that TPN reduction is taking place at a more rapid rate in the preparation from erythrocytes of the normal subject than in the preparation from erythrocytes of the sensitive subject.

**Procedure [150].** After removal of plasma and buffy coat, red cells are washed twice in cold isotonic KCl at pH 7.4 and are lysed by freezing and thawing twice. The assay system consists of 0.1 M  $\text{MgCl}_2$ , 0.5 ml 0.25 M glycylglycine buffer pH 7.6, 0.5 ml  $2.3 \times 10^{-4}$  M TPN, 0.1 ml 0.5 M glucose 6-phosphate, 0.5 ml hemolyzate, water to 2.5 ml. Activity is expressed as  $\Delta \text{O.D.}$  ( $\lambda = 340 \text{ m}\mu$ ) per min per gm Hb or per ml RBC or per 10<sup>12</sup> RBC.

\*The substitution of 0.05 M glucose 6-phosphate is satisfactory and much less expensive.

*Dye linked assay [125 153]*

A quick screening test has been described in which the decolorization (reduction) under oil of brilliant cresyl blue by a hemolyzate supplied with FPN and glucose 6-phosphate is observed with the naked eye. Experience with this test is still limited.

It appears certain that simpler screening methods for the detection of drug sensitive individuals will be developed and that more exact methods for quantitation of enzyme activity such as that of Glock and McLean [122] will be adapted to red cells for more precise studies.

## GENETICS OF DRUG SENSITIVITY

The availability of *in vitro* methods for the detection of the red cell abnormality of drug sensitive subjects has made possible extensive studies of the genetics of this defect. The mode of inheritance has been elucidated beautifully by Childs et al [126].

## DOMINANCE

The defect has been found in as many as three successive generations [74 126] (Fig 32.7 Family 12 LA). For this reason transmission as a recessive characteristic is extremely unlikely.

## SEX DISTRIBUTION

Several curious features have come to light regarding the distribution of the erythrocyte defect between the sexes. It was noted that severe GSH instability or severe glucose 6-phosphate dehydrogenase deficiency occurred most commonly among males [54 65 74 126]. This appeared to support the clinical observation that severe hemolytic anemia on exposure to fava beans occurs more frequently among men than among women [47]. It was also found that intermediate degrees of GSH instability occurred among female relatives of sensitive subjects [54 74 126 154] and that the females usually had intermediate degrees of enzyme deficiency [54, 66 74].

## GENETIC BASIS OF THE SEX DISTRIBUTION

It is apparent from the observations that the genetics of this defect is not simple autosomal inheritance; the defect is either sex linked or sex limited. The available pedigrees reveal that almost invariably it is the mother of affected males who carries the disorder if it is demonstrable in either parent [47 54 74 126]. This finding makes it most probable that the defect is sex linked rather than sex limited [126]. The latter possibility should not result in any alteration in the ratio of mothers and fathers of propositi affected.

available pedigrees show clearly that this is not the case. Thus some females with marked GSH instability and glucose 6 phosphate dehydrogenase deficiency must be heterozygous because they have borne boys who are not affected [cf Fig 32 7 Family K II—A K and E K have produced four negative sons (III—J K P K Go K and G K)]. Further the fact that neither parent of some propositi has the defect demonstrable *in vitro* indicates that the gene can be carried without causing a detectable disorder of the red cell which is demonstrable *in vitro*. Interestingly it has been found that the erythrocytes of at least some such individuals with a negative GSH stability test undergo hemolysis when primaquine is given [14]. The glucose 6 phosphate dehydrogenase content of the red cells of such patients has not been reported.

#### GLUCOSE 6 PHOSPHATE DEHYDROGENASE ACTIVITY IN CELLS OTHER THAN ERYTHROCYTES

Because glucose 6-phosphate dehydrogenase deficiency is genetically determined it would appear reasonable that the synthesis of this enzyme might also be impaired in tissues other than the red blood cell. Studies based on the intravenous administration of specifically labeled glucose show retarded appearance as  $\text{CO}_2$  of the 1 carbon of glucose given to sensitive subjects and thus appear to support this supposition. Only a very limited amount of direct data on enzyme activity in cells other than erythrocytes is available however. Liver biopsies from two sensitive subjects showed less enzyme activity than those of four nonsensitive controls. The difference was much smaller than that observed when red cell enzyme activities were compared. The glucose 6-phosphate dehydrogenase activity of the leukocytes of 14 sensitive subjects did not differ appreciably from that of 31 controls [120c]. Blood platelets from sensitive subjects in contrast have a marked reduction in glucose 6 phosphate dehydrogenase activity [120b]. These findings are compatible with the concept that the enzyme produced by sensitive subjects is abnormal and is more susceptible to damage than normal enzyme [12a]. Nucleated cells such as leukocytes and liver cells could maintain enzyme activity at normal or near normal levels by continued resynthesis but non nucleated cells such as platelets and red cells unable to synthesize more enzyme as they aged would become progressively enzyme-depleted.

#### INCIDENCE AND DISTRIBUTION OF DRUG SENSITIVITY

Two types of information are available on which to base estimates of the incidence and distribution of glucose 6-phosphate dehydrogenase deficiency. The first is the evaluation of reports in the literature of acute hemolytic anemia following the ingestion of drugs. The second consists of

population surveys using the methods developed for *in vitro* detection of the red cell abnormality of sensitive individuals

Some of the more significant information is summarized in Table 32.3. The highest incidence in a single group is in a relatively small series of Iraqi Jews. Twenty per cent of this population has the defect. Other groups of Sephardic Jews have a lower but still quite appreciable incidence. High incidence has been consistently reported in American Negroes among whom the gene frequency seems to be approximately 10 per cent judging from incidence of positive *in vitro* tests and incidence of hemolysis in males. Presumably the incidence would be similarly high in West Africa. A positive GSH stability test result has been demonstrated in a native Nigerian woman presently a student in the United States [117]. The failure to observe hemolysis among Sudanese villagers given pamaquine and the 2 per cent incidence of positive GSH stability test results among Bantu natives lead one to conclude that the incidence of the defect is lower in certain parts of Africa. The incidence of the defect is appreciable in India, Formosa and perhaps Thailand, but lower among the Chinese. Information about the distribution of the defect but not its incidence may be obtained from a recent exhaustive review of the distribution of favism by Sansone et al. [47]. In addition to numerous reports from Sardinia, cases have been reported from almost every region in Italy, from Greece, Israel, Lebanon, Turkey, Spain, Bulgaria and even from West China.

Because the distribution of the defect parallels roughly the distribution of malaria, it has been suggested that glucose 6-phosphate dehydrogenase deficiency like sickle cell hemoglobin may confer resistance to malaria [163]. Preliminary studies appear to support this point of view [167b].

### A CLOSELY RELATED DEFECT

When drug sensitive erythrocytes are not challenged with drug their survival is normal. Observations by Newton et al. [163, 169] confirmed by others [170, 171] suggest that certain subjects who clinically are suffering from nonspherocytic hemolytic anemia have the same enzymatic abnormality as drug sensitive subjects. In common with drug sensitive subjects their red cells have unstable GSH and have markedly diminished glucose 6-phosphate dehydrogenase activity. Heinz body formation in their red cells after incubation with acetylphenylhydrazine is also identical with that seen in drug sensitive subjects. They differ from drug sensitive subjects in that shortening of red cell survival as measured by the  $\text{Cr}^{51}$  technique occurs in these subjects and in their mothers [169, 171]. Furthermore this disorder differs from drug sensitivity in that all the individuals affected have been Caucasian (in one case of Irish stock). Other cases of hemolytic anemia reported recently [133] may fit into

this category. It seems most likely that this form of nonspherocytic hemolytic anemia represents the effect of another much rarer genetic mutation which also affects glucose 6-phosphate dehydrogenase activity, but perhaps through another mechanism and perhaps to a much greater degree.

## SUMMARY

1 When certain ordinarily harmless drugs are administered to susceptible persons, an acute hemolytic reaction results. Among these are 8-aminoquinoline antimalarials such as primaquine, certain sulfonamides, acetanilid, phenacetin, Iuradantin, and many others. Persons with a history of favism have the same red cell abnormality.

2 When sensitive persons receive the drug, the older members of the red cell population are rapidly destroyed. The hemolytic anemia then ceases, even while drug administration is continued, because young erythrocytes are resistant to destruction.

3 Susceptibility to drug-induced hemolysis is due to an intrinsic abnormality of the erythrocyte.

4 Drug-sensitive red cells have reduced glucose 6-phosphate dehydrogenase activity. This enzyme normally catalyzes the oxidation of glucose 6-phosphate, which is coupled to reduction of TPN. TPNH in turn maintains glutathione in its reduced form (GSH). Drug-sensitive red cells are unable to reduce TPN at a normal rate. Probably as a result of this enzymatic defect, the GSH content of sensitive cells is decreased, and when sensitive cells are challenged with drug *in vivo* or *in vitro*, a further decrease in GSH concentration takes place. GSH may be an important agent in maintaining structural integrity of the red cell, as may be TPNH, but the ultimate way in which glucose 6-phosphate dehydrogenase deficiency is linked to red cell drug susceptibility is unknown.

5 Drug-sensitive red cells can be detected *in vitro* by assaying them for glucose 6-phosphate dehydrogenase activity. They can also be detected by incubating red cells under standardized conditions with acetylphenylhydrazine and by measuring the reduced glutathione content, or by observing the pattern of Heinz body formation.

6 The red cell abnormality of drug sensitivity is an inherited, sex-linked dominant trait. Marked variability in the degree of penetrance is observed among affected females who are heterozygotes. The defect is widely distributed; it is common among American Negroes, Sephardic Jews, and Sardinians.

7 While red cells from patients with this defect have normal life spans, unless challenged by drug, a similar biochemical abnormality has also been described in a few patients with non-spherocytic hemolytic anemia.

## Chapter 33

### The Hereditary Methemoglobinemias\*

---

*Park S. Gerald*

#### DEFINITION

Hereditary methemoglobinemia or hereditary methemoglobinemic cyanosis is a rare condition. More than one hundred cases have been reported in the literature. The disease has been described in Caucasians, Eskimos, and Chinese. Many of the patients have been of Greek stock.

The major feature of the disorder is a diffuse persistent slate gray cyanosis which is present from early infancy and unassociated with clubbing of the fingers or significant cardiac murmurs. Methemoglobin comprises 20 to 50 per cent of the total hemoglobin. Compensatory polycythemia and associated reticulocytosis are occasionally observed. The disease is frequently well tolerated and patients may reach an advanced age. Cardiac and respiratory distress are conspicuously absent although exertion may cause dyspnea, palpitation, easy fatigability, and severe headache. The conjunctival and retinal veins may be congested.

The blood has a chocolate hue and fails to turn a normal red color upon oxygenation. This is attributable to the presence in the erythrocytes of excessive amounts of methemoglobin (ferrihemoglobin), an oxidation product of hemoglobin.

The increased concentration of methemoglobin in this disorder occurs in the absence of any exogenous methemoglobin-producing substances. This serves to distinguish this syndrome from the acquired methemoglobinemias. Since normal individuals have small but definite amounts of methemoglobin in their blood, it is apparent that the formation of methemoglobin is a normal process. Accordingly, it must be assumed that there is a physiologic reducing system which can reconvert methemoglobin to hemoglobin.

The experimental work included in this report was completed while the author was a Research Fellow in the Department of Pediatrics, Harvard Medical School and the Department of Medicine, Children's Medical Center, Boston, Mass.

bin to hemoglobin. The existence of abnormal levels of methemoglobin indicates an imbalance between the oxidative and reductive processes.

### HISTORICAL INTRODUCTION

The first reports of cyanosis due to an abnormal blood pigment (presumably methemoglobin) stressed a supposed relationship with gastrointestinal disturbances in the descriptive phrase "enterogenous cyanosis" [1]. It was not until 1930 when Jitarczek et al. described an adult with cyanosis from early childhood [2] that the possibility of constitutional metabolic disorder was seriously entertained. The familial nature of the syndrome was suggested by Hitzemberger [3] and later confirmed by Bensley et al. in 1938 [4]. The latter authors in their report surveyed the world literature on hereditary methemoglobinemia and found only four sporadic cases of the idiopathic (metabolic) type in addition to the two reports of familial cases then available. Probably as a result of the decline in usage of methemoglobin producing drugs and of the increased interest in metabolic disease in general, a remarkable number of new cases of the idiopathic type has been recorded since their survey. More than 30 pedigrees are known which involve at least two affected members and a comparable number of isolated sporadic cases can be listed.

The major efforts to elucidate the fundamental mechanism of this disease have been chiefly those of the English worker Gibson. His studies of affected individuals from several families have demonstrated a defect in the enzyme system which is normally responsible for maintaining the hemoglobin in the reduced state [5]. This defect appears to be transmitted recessively.

Quite recently it has become apparent that Gibson's explanation is inapplicable to many of the reported cases. The first note of discrepancy was introduced by the studies of Hörlein and Weber of a German family in which the disorder could be attributed to a dominantly transmitted abnormality in the hemoglobin itself [6]. The dominant inheritance of congenital methemoglobinemia, particularly in Greek populations, has been stressed by Codrains [7]. A number of North American families also demonstrating dominant transmission have now been studied and in all an abnormal hemoglobin has been found with properties quite sufficient to explain the methemoglobinemia (see below) [8]. This group of abnormal hemoglobins is known as the Hb M type pigments, after the example of Singer [9] who applied the designation Hb M to the hemoglobin discovered by Hörlein and Weber [6]. The pigments are all characterized by the anomalous nature of their methemoglobin as indicated by the abnormal absorption spectrum of the derivative.

From the foregoing it is evident that hereditary methemoglobinemia is not a single disease but rather a group of diseases. On the basis of

current information three categories of differing etiology may be postulated (1) formation of an abnormal methemoglobin resistant to reduction, (2) a deficiency in the erythrocytic reducing system, with accumulation of "normal" methemoglobin, and (3) abnormal endogenous formation of oxidizing substances, with increased production of methemoglobin beyond the capacity of the system which normally maintains the hemoglobin in the reduced state.

## CHEMISTRY OF METHHEMOGLOBIN

### "Normal" Methemoglobin

Methemoglobin is the oxidized derivative of hemoglobin in which the iron of the four heme groups is changed from the usual ferrous to the ferric state. As a consequence the iron is no longer able to complex with oxygen. Methemoglobin is accordingly unable to serve as a respiratory pigment. These statements apply with equal validity to the methemoglobin derived from all known hemoglobins including the abnormal human hemoglobins and the several molecular species that comprise "normal" hemoglobin.<sup>1</sup>

As is true of heme pigments in general, methemoglobin has a characteristic spectral absorption curve. Employed in identification and measurement, its use rests upon the implicit assumption that the methemoglobins prepared from different hemoglobins are identical or very nearly so in their spectral properties. This assumption is quite valid for the various components of normal human hemoglobin and for most abnormal hemoglobins, but the Hb M-type pigments must be excepted. One should be aware that the absorption curve of methemoglobin changes with hydrogen ion concentration. That observed at pH 7.0 and below corresponds to the acidic form of methemoglobin, and that at higher pH values to alkaline methemoglobin.

Methemoglobin takes part in two major categories of reactions which are of particular interest here. It may be reduced to hemoglobin which can then combine with oxygen (to form oxyhemoglobin) or it may complex directly with a number of substances, especially nitrogenous compounds such as cyanide. In either case the spectrum is altered to an absorption pattern characteristic of the resulting compound. Under usual conditions these reactions affect equally all four heme groups of the molecule and are accompanied by a change in the total charge of the molecule. In the case of cyanmethemoglobin the addition of the cyanide ion neutralizes one positive charge of each heme group (since one univalent anion combines with each ferric atom) and the net charge is equal to that of oxyhemoglobin.<sup>2</sup>

<sup>1</sup> The heterogeneity of normal hemoglobin is discussed in detail in the section on the hemoglobinopathies (see Chap. 34).

<sup>2</sup> Heme-linked ionizations are not considered in this discussion.

*Gasometric Methods of Analysis*

The loss of oxygen-combining power may be used as a measure of the amount of methemoglobin by comparing the total oxygen capacity with that expected from the total amount of heme pigments present. The latter is separately determined by estimation of the heme groups (as by iron analysis or as acid hematin). This method usually overestimates the concentration of methemoglobin since of necessity the result also includes other non-oxygen-combining pigments such as sulfhemoglobin. This technique indicates that not more than 2 per cent of the hemoglobin of normal blood can be in the methemoglobin form [10].

*Spectroscopic Methods of Analysis*

In essence all spectroscopic methods assay the amount of methemoglobin by quantitating the spectral change when methemoglobin is chemically altered either by complex formation or by reduction. The most commonly used technique is that of Evelyn and Malloy [11]. The methemoglobin is reacted with cyanide and the change in light absorption at 632 m $\mu$  is measured. This method is quite specific in the absence of the Hb M-type pigments. The normal concentration of methemoglobin obtained with cyanide techniques is less than 2 per cent of the total pigment [12].

Since Hb M-type pigments in the methemoglobin form have abnormal absorption spectrums the usual quantitative spectroscopic tests give erroneous values for the degree of methemoglobinemia in Hb M disease. With certain varieties of Hb M disease the circulating pigment does not react with cyanide and a negative result for methemoglobin is obtained in spite of the obvious cyanosis of the patient. Qualitative spectroscopic tests which depend upon identification of the characteristic absorption band (at 632 m $\mu$ ) will likewise not give the expected finding. In many cases of Hb M disease no abnormal absorption band will be seen with the hand spectroscope.

## HEREDITARY METHEMOGLOBINEMIA ASSOCIATED WITH THE SPECTROSCOPICALLY ABNORMAL METHEMOGLOBINS (THE Hb M DISORDERS)

*Electrophoretic and Spectrochemical Behavior of Normal Hemolyzates*

Since the isolation of the Hb M-type pigments has been accomplished only very recently the information concerning them is relatively limited and is confined largely to the electrophoretic and spectroscopic behavior of certain derivatives. A few preliminary remarks concerning the electrophoretic behavior of hemolyzates prepared from the blood of normal individuals is a necessary introduction to this subject (a more extensive discussion will be found in the section on the hemoglobinopathies Chap

34) By utilizing various techniques, the hemoglobin of normal hemolyzates can be shown to contain a minimum of three distinct components (Hb A, Hb A<sub>2</sub>, and Hb F). These probably differ considerably in their intimate chemical structure. Under the conditions used in the study of the Hb M-type pigments (electrophoresis on starch block at pH 7.0) normal hemolyzate migrates as a single band toward the cathode. Normal hemolyzate also migrates as a single band (toward the cathode) after oxidation to methemoglobin, although now the rate of migration is more rapid because of the increase in positive charge. After neutralization of the charge by treatment with cyanide, the pigment (cyanmethemoglobin) migrates as a single band with essentially the same mobility as oxyhemoglobin.

#### *Electrophoretic and Spectrochemical Behavior of the Hb M-Type Pigments*

In the blood from all individuals exhibiting methemoglobinemia of the dominantly transmitted type so far examined, electrophoresis of

TABLE 33-1 SPECTROSCOPIC AND CHEMICAL PROPERTIES OF THE Hb M-TYPE PIGMENTS (IN M/15 SODIUM PHOSPHATE BUFFER, pH 6.5)

| Pigment              | Maxima in visible region $m\mu$ | Gross color of electrophoretic band | Cyanmethemoglobin spectrum† |
|----------------------|---------------------------------|-------------------------------------|-----------------------------|
| Methb A              | 502-632                         | Brown                               | Normal                      |
| Methb M <sub>B</sub> | 495-602                         | Gray                                | Abnormal                    |
| Methb M <sub>B</sub> | 492-602                         | Green                               | Normal                      |
| Methb M <sub>M</sub> | 500-602                         | Gray-green                          | Normal                      |

Hb M Boston type (Hb M<sub>B</sub>) was isolated from the family reported by Gerald et al [13]. Hb M Saskatoon type (Hb M<sub>S</sub>) from that of Baltzan and Sugarman [14] and Hb M Minneapolis type (Hb M<sub>M</sub>) from that of Pesciotta and Hinz [15].

† Those pigments with an abnormal cyanmethemoglobin spectrum are not associated with increased concentration of methemoglobin in the patient when the methemoglobin is determined by its reaction with cyanide.

hemolyzates under appropriate conditions has disclosed an abnormal pigment. These pigments collectively known as the Hb M-type pigments are anomalous in that the relative electrophoretic mobilities of the oxyhemoglobin, methemoglobin, and cyanmethemoglobin derivatives differ from that predicted by experience with normal hemoglobin (Fig. 33-1). The untreated hemolyzate migrates as a single band. After conversion of all the pigment to methemoglobin by treatment with ferricyanide, two distinct bands are observed. After conversion to cyanmethemoglobin, a single band is again observed which has a mobility comparable to that of the initial hemolyzate. These findings are incompatible with the charge differences among oxyhemoglobin, methemoglobin, and cyanmethemo-

globin derivatives as previously described, and are best explained by assuming that the increase in positive charge of the methemoglobin, over that present in the oxyhemoglobin and cyanmethemoglobin forms is less for the Hb M-type pigments than for normal hemoglobin. Very little or no charge difference apparently exists between the normal and the

Fig. 33-1. Electrophoretic behavior on starch block of a hemolyzate containing both Hb M and Hb A: (a) Untreated hemolyzate; (b) after conversion to methemoglobin; (c) after conversion to cyanmethemoglobin. (Electrophoresis in sodium phosphate buffer pH 7.0; ionic strength 0.10.)

abnormal fractions of the hemolyzate when present as oxyhemoglobin or cyanmethemoglobin—a significant difference appears only when the methemoglobins are compared.

The electrophoretically purified Hb M-type pigments have been studied spectroscopically and are most unusual [8]. The absorption maxima of the acidic methemoglobin form of three different Hb M-type pigments are given in Table 33-1. These are designated Hb M<sub>1</sub>, Hb M<sub>2</sub>,

instance the usual methemoglobin band could not be demonstrated in a patient who was intensely cyanotic [20]. Finally, the pedigree of sulfhemoglobinemia described by Miller [26] and that of idiopathic cyanosis by Lutembacher [27] cannot be distinguished from instances of Hb M<sub>s</sub> disease by the tests reported.

### *Erythrocyte Metabolism in the Hb M Diseases*

The limited studies performed to date have failed to demonstrate any abnormality of the erythrocyte enzyme systems. The rate of reduction of methemoglobin with cells treated *in vitro* with oxidizing agents has not differed significantly from that observed with normal red cells even under the conditions which successfully demonstrate the defect in the enzymatic variety of hereditary methemoglobinemia [28]. Pisciotta et al. [16] observed in one patient<sup>4</sup> that the concentration of methemoglobin in freshly shed blood did not change after incubation of the cells with fresh normal plasma or with glucose. Also if the concentration of methemoglobin in the cells was first increased to 90 per cent (from the *in vivo* level of 30 per cent) by treatment of the cells with nitrate incubation with fresh normal plasma resulted in a decrease of methemoglobin to the original 30 per cent value in a few hours. This result is in accord with a normal enzyme system which can convert normal methemoglobin to the reduced state but which is less able to cope with abnormally reactive oxidized hemes of the Hb M-type pigments.

The life span of the erythrocyte as determined by reticulocyte count and serum bilirubin is normal in the Hb M diseases. The one reported exception to this was in a patient possessing both a Hb M-type pigment and an additional unidentified (Hb C like) hemoglobin [21].

### *Clinical Physiology*

On the basis of the proposed theory it is reasonable to expect that the methemoglobin formed *in vivo* in Hb M diseases would be derived almost solely from abnormally reactive hemes of the Hb M-type pigments. The failure to detect abnormal blood concentrations of methemoglobin by the Evelyn and Malloy test in two families is consistent with this [13-21]. As a result there is an upper limit to the impairment in oxygen combining power which on this basis should not exceed one-half the concentration of the Hb M-type pigment. The abnormal reactivity is also responsible for the resistance to ascorbic acid and methylene blue therapy seen in some cases of Hb M disease [13-21].

A Hb M-type pigment (Hb M<sub>s</sub>) has since been isolated by the author from the blood of this patient samples of which were generously made available by Dr. Pisciotta.

*Genetics*

Since the abnormality in the Hb M-type pigments is limited to the globin of the molecule the e hemoglobins may be classed with the more common abnormal hemoglobins (see Chap 34). Like them the Hb M-type pigments have been transmitted as a codominant character involving both sexes in all the pedigrees adequately studied. No abnormality has been commonly associated with the abnormal hemoglobin except the e secondary to its presence. All reported cases have come from European and Mediterranean populations.

### HEREDITARY METHEMOGLOBINEMIA ASSOCIATED WITH A DEFICIENCY OF THE METHEMOGLOBIN REDUCING SYSTEM

#### *Methemoglobin Reduction in the Normal Human Erythrocyte*

It is assumed that the small but definite amount of methemoglobin in normal blood represents an equilibrium between the processes causing methemoglobin formation and those accomplishing its removal. Except for the effect of oxygen little information is available concerning the factors responsible for the normal formation of methemoglobin; hence the following remarks will be confined to the methemoglobin reducing process. Since there is a significant interspecies variation in these reactions the discussion will be confined to results obtained in studies of human erythrocytes.

The reduction of methemoglobin in the normal human red cell proceeds slowly in a saline suspension but is increased by the addition of glucose to the medium and nearly equally so by the addition of lactate [29]. With either substrate the reduction is accompanied by the formation of an equivalent amount of pyruvate [29] (see Fig 33-2 for a condensed outline of the glycolytic pathway). Methemoglobin reduction is probably linked to glycolysis through reduced diphosphopyridine nucleotide (DPNH) [29]. Evidence for this is the inhibitory action of iodoacetate on methemoglobin reduction when glucose is the substrate and its lack of effect when the glucose is replaced by lactate (see Fig 33-2). In keeping with this scheme is the failure of fluoride to affect reduction in the presence of glucose [29].

Certain autooxidizable dyes such as methylene blue (MB) are capable of accelerating the reduction of methemoglobin in the presence of the proper substrate. When MB is added along with glucose a tenfold increase is obtained. The amount of pyruvate (or of phosphoglycerate when fluoride is present) formed under these conditions is considerably less than that expected from the amount of methemoglobin reduced in contrast to the results obtained without MB. The MB thus appears to

activate a metabolic pathway which is not operative in its absence [20] From studies of normal and hereditary methemoglobinemic erythrocytes, Gibson concluded that this pathway was the hexose monophosphate shunt [20] the initial and pertinent steps of which are given in Fig 33-3

Fig 33-3 Condensed outline of the glycolytic pathway [30] The omission of intermediate reactions is indicated by a double arrow

Fig 33-3 Initial reactions of the hexose monophosphate shunt [31]

It should be noted that TPNH rather than DPNH is produced by this reaction. Indirect evidence supporting Gibson's contention is now available from the studies of cells deficient in glucose 6 phosphate dehydrogenase (C 6 I D). Red cells deficient in C 6-I D activity are concomitantly defective in reducing methemoglobin in the presence of glucose plus MB [32-33].

The majority of investigators though by no means all believe that the reaction between methemoglobin and reduced pyridine nucleotides is an enzymatically controlled step. Kiese obtained direct evidence in favor of this by preparing an extract from horse erythrocytes which was capable of reducing methemoglobin in the presence of TPNH [34]. His term for the enzyme *methemoglobin reductase* has since been adopted in the current literature for the human counterpart. Gibson assumed the existence of such an enzyme but postulated that two comparable systems were present, one active toward TPNH and the other toward DPNH [29]. Recently Huennekens et al isolated an enzyme (which they called methemoglobin reductase) from human erythrocytes which catalyzed the reaction of methemoglobin with TPNH [35]. Unexpectedly this preparation had a significant though lesser (one-fifth as great) activity with DPNH.

A preliminary account is now available of an investigation furnishing direct evidence for the presence in normal human erythrocytes of an enzyme capable of reducing methemoglobin which has a DPNH preference [36]. In this and in other properties it differs significantly from the methemoglobin reductase of Huennekens et al. Its probable importance in the reduction of methemoglobin is indicated by the observation that this particular enzyme is deficient in the erythrocytes from the few patients with hereditary methemoglobinemia (of the recessively transmitted type) so far studied.

#### *Methemoglobin Reduction in Erythrocytes from Patients with Enzymatic Hereditary Methemoglobinemia*

It has long been suspected that the abnormality in hereditary methemoglobinemia is an intrinsic disorder of the erythrocyte. Lian et al found that methemoglobin has little or no tendency in vitro to disappear spontaneously from hereditary methemoglobinemic cells [37] in contrast to the rapid reduction observed with cells from toxic methemoglobinemia. A more dramatic and elaborate confirmation of this clinical conclusion was obtained by Eder et al who transfused cells from a congenitally methemoglobinemic individual into a patient with aplastic anemia and demonstrated the persistence of methemoglobin within the erythrocytes despite their being in a foreign circulation [38].

Incubation of erythrocytes from patients with hereditary methemoglobinemia of the enzymatic type in saline containing glucose is not associated with the rapid reduction of the methemoglobin which is seen with normal cells in which methemoglobin has been produced by chemical treatment. This is observed in spite of apparent adequacy of the glycolytic enzyme systems in such cells [29]. Preservation of glycolysis is inferred from the rapid reduction of pyruvate to lactate in the presence of glucose plus fluoride as in normal cells. However in the presence of both MB and glucose, normal and hereditary methemoglobinemic cells are equally

activate a metabolic pathway which is not operative in its absence [29]. From studies of normal and hereditary methemoglobinemic erythrocytes Gibson concluded that this pathway was the hexose monophosphate shunt [29], the initial and pertinent steps of which are given in Fig. 33-3.

Fig. 33-2 Condensed outline of the glycolytic pathway [30]. The omission of intermediate reactions is indicated by a double arrow.

Fig. 33-3 Initial reactions of the hexose monophosphate shunt [31].

It should be noted that TPNH rather than DPNH, is produced by this reaction. Indirect evidence supporting Gibson's contention is now available from the studies of cells deficient in glucose 6-phosphate dehydrogenase (G-6-PD). Red cells deficient in G-6-PD activity are concomitantly defective in reducing methemoglobin in the presence of glucose plus MB [32, 33].

definite shift to the left of the curve was observed [3 43-44] and in one instance a slight shift [2] but in two no alteration could be demonstrated [38 45] Gibson has emphasized the significance of this discrepancy and has suggested that absence of the alteration in the oxygen dissociation curve implies an uneven distribution of methemoglobin i.e. some erythrocytes contain only methemoglobin and the remainder only reduced (ferro) hemoglobin [5] It is of course possible that these are two groups of cases which differ basically in their etiology

### *Clinical Physiology and Therapy*

The defect in oxygen carrying capacity of the blood of the patients has not been sufficient to cause symptoms referable to oxygen deficiency except in a few cases nor has there been a direct effect upon the survival of the red cell

The therapy of this disease is based upon the promotion of *in vivo* reduction of the methemoglobin by administration of MB or ascorbic acid Although ascorbic acid is nearly as effective as MB its mode of action is still but poorly understood MB administered intravenously causes an abrupt fall of the methemoglobin concentration to near normal values while ascorbic acid administration is associated with a gradual decline to a steady level which is still somewhat above normal [45] Alleviation of the cyanosis with either of these agents is obtained only so long as therapy is continued

The intensity of cyanosis varies with the diet and with the season which may possibly be a reflection of ascorbic acid intake The onset of cyanosis is variable In a few cases it has been observed immediately or a few hours after birth [46] In others it has not been noticed until adolescence [4] Whether this is related to diet or to exposure to methemoglobin promoting agents is not known

Although the appearance of cyanosis in early infancy suggests the very real possibility of hypoxic brain damage this complication has been reported relatively infrequently [3 46-49] The occurrence of mental deficiency in all the methemoglobinemic children (total of six affected) of two pedigrees [47, 48] suggests a unique difference in the etiology of their methemoglobinemia

### *Genetics*

Until recently information on the inheritance of hereditary methemoglobinemia was confused by pedigrees documenting both recessive and dominant transmission Some of the families with dominantly inherited cyanosis are now known to be affected with one of the Hb M diseases and in many of the remaining families indirect evidence suggests that they also belong to this same category On the basis of present information it seems reasonable to anticipate that the two inheritance patterns will

able to reduce methemoglobin. It was this contrasting behavior which led Gibson to postulate that MB activates an otherwise inactive reduction pathway [29]. On the assumption that reduction of methemoglobin (in the absence of MB) by DPNH is controlled by a specific DPNH dependent enzyme, Gibson considered that a deficiency of this enzyme was the basis of the defect in hereditary methemoglobinemia [29]. Gibson developed an assay method supposedly specific for this erythrocytic enzyme and was able to demonstrate a marked deficiency in five methemoglobinemic patients and a slight deficiency in two others [29-39].

As previously mentioned, further evidence is now available to corroborate Gibson's hypothesis that methemoglobin reduction is normally controlled by a DPNH-dependent enzyme [36]. The direct demonstration of this enzymatic activity was made possible by the development of an improved assay system. Scott and Griffith have shown that the reaction between 2,6-dichlorobenzene indophenol and DPNH is catalyzed by an enzyme present in the hemolysates from normal individuals. The hemolysates from patients with hereditary methemoglobinemia, however, failed to exhibit such activity [40].

Fig 33-4 The effect of methemoglobin as formed by ferricyanide on the oxygen dissociation curve of human hemoglobin. 0.6 M phosphate buffer, pH 7.4. With increasing methemoglobin the dissociation curve shifts to the left [41].

### The Oxygen Dissociation Curve in Hereditary Methemoglobinemia

Methemoglobin is unable to bind oxygen because of the altered state of the iron. In addition, there is an indirect effect resulting from the interaction of the four heme groups in the hemoglobin molecule. Oxidation of one of the heme groups in a given

molecule affects the tenacity of the binding with oxygen of the remaining unoxidized groups. This is one manifestation of a more general phenomenon known as heme-heme interaction. This is most clearly demonstrated by plotting oxygen saturation of the hemoglobin against oxygen pressure of the gaseous phase—the oxygen dissociation curve. The heme-heme interaction theory predicts that following partial oxidation of the hemes, a change in shape of the curve and a shift to the left (greater saturation at lower oxygen tension) will occur. This prediction was confirmed by the experimental findings of Darling and Roughton with hemoglobin after partial oxidation *in vitro* [41] (Fig 33-4).

The oxygen dissociation curve in hereditary methemoglobinemia has been determined by seven different investigators. In four instances a

(b) a deficiency in the erythrocyte enzyme system which maintains hemoglobin in the unoxidized state and (c) abnormal endogenous formation of substances capable of oxidizing hemoglobin to methemoglobin. Although only a single possible case is available to illustrate the last category the first two pathogenetic mechanisms appear to be of nearly equal importance in the causation of hereditary methemoglobinemia.

3 The frequency of abnormal methemoglobins resistant to reduction has only recently been realized. These methemoglobins which are the oxidation products of a group of different hemoglobins categorically designated the Hb M-type pigments are unique in their electrophoretic and spectrochemical behavior. Their spectral absorption curves differ from that of methemoglobin prepared from normal human blood and hence from that of any other vertebrate methemoglobin. Consequently the usual spectroscopic and chemical tests for methemoglobin may not be applied to blood containing a Hb M-type pigment without risking quantitative or even qualitative error.

Since the molecular abnormality of the Hb M-type pigments lies in the globin these may properly be considered as further examples of the abnormal hemoglobins. As might be expected in pedigrees exhibiting this condition the cyanosis is transmitted as a dominant character.

4 The second major pathogenetic category of hereditary methemoglobinemia derives from a deficient intracerythrocytic enzyme system for reducing methemoglobin. Present evidence favors the theory that the disease arises from a deficiency of a diphosphopyridine nucleotide-dependent enzyme which is normally responsible for reducing methemoglobin.

5 Alternatively hereditary methemoglobinemia of the enzyme deficiency type may be a heterogeneous group of conditions. Of particular interest in this regard is the seemingly inextricable association of hereditary methemoglobinemia and mental defect in some families and the unexpected finding of oxygen dissociation curves without the shift to the left obtained in others.

6 The two main categories of hereditary methemoglobinemia differ not only in spectroscopic findings but also on genetic grounds. It seems probable that the pedigrees with dominant transmission of cyanosis represent instances due to a Hb M type pigment and that the recessive variety is due to erythrocytic enzyme deficiency.

divide the cases into Hb M disease (dominant) and the enzyme deficiency variety (recessive)

When a rare disease is recessively inherited the proportion of pedigrees derived from consanguineous matings is usually appreciable. Surprisingly, only a single instance of consanguinity has been noted among the pedigrees of hereditary methemoglobinemia of the recessive type [49]

Like the Hb M diseases the enzyme deficiency variety has been described only in populations with a light complexion. This may reflect the difficulty of detecting cyanosis in a dark-skinned person. Both European and non-European peoples [40, 50] have been affected. No predilection for either sex has been noted.

### CONGENITAL METHEMOGLOBINEMIA DUE TO AN EXCESS OF ENDOGENOUS OXIDIZING SUBSTANCES

At present this category is largely hypothetical. One case has been reported which may fall within it. Fishberg has described a patient with idiopathic methemoglobinemia and severe cyanosis (no clinical details were given) who excreted large amounts of benzoquinoneacetic acid in the urine even while on a normal diet [51]. Methemoglobin concentrations as high as 20 per cent were observed during the period of benzoquinoneacetic acid excretion and the actual blood concentration of methemoglobin varied roughly with the output of this substance. Ascorbic acid administration rapidly abolished both the excretion of benzoquinoneacetic acid and the methemoglobinemia. It was concluded by Fishberg that the methemoglobinemia was the direct result of the oxidation of the hemoglobin by benzoquinoneacetic acid. Although the data are not adequate to determine whether the presence of the latter resulted from a metabolic disorder or from a transient ascorbic acid deficiency, the frequency of ascorbic acid deficiency without concomitant cyanosis suggests that a metabolic error was present in Fishberg's case.

### SUMMARY

1 Hereditary methemoglobinemia is characterized by chronic cyanosis associated with increased amounts of intravascular methemoglobin, the oxidation product of hemoglobin. Since small amounts of methemoglobin may be identified in normal blood, it is believed that an equilibrium exists between the processes responsible for oxidation of the hemoglobin to methemoglobin and those which facilitate the reverse reaction. Hereditary methemoglobinemia is the result of a hereditary imbalance in these two competing processes.

2 At present three different pathogenic mechanisms appear possible:  
(a) the formation of an abnormal methemoglobin resistant to reduction,

## ADULT AND FETAL HEMOGLOBIN

About one-hundred years ago von Korbër [1] noticed that the blood of the adult is more easily denatured by alkali than that from the placenta. He concluded that there are two human hemoglobins—adult and fetal. These are now designated A and F. Hemoglobin F is present in infants at birth when it varies in concentration from approximately 60 to 90 per cent. It then gradually disappears from the circulation and by the age of 4 months only traces persist.

Jonxis [2] has pointed out that the presence of Hb F in the blood of normal children over 11 months old may be explained only by the synthesis of this pigment after birth. Formation of Hb F may persist in pathologic states which begin at an age when Hb I is still being produced and if the cause of the infantile disorder usually an anemia is not removed Hb F may still be found in adult life. This was first observed in thalassemia [3-6] but was later also found in sickle cell anemia [7] and other hemoglobinopathies. The phenomenon is not specifically associated with this group of disorders but can be observed in many other syndromes such as spherocytic jaundice, leukemia and nutritional anemias.

The numerous differences between adult and fetal hemoglobins have been summarized by White and Beaven [8] and by Bethe [9]. These include differences in solubility, ultraviolet spectrum and resistance to alkali denaturation. There may be differences also for oxygen affinity and in antigenic activity. Hemoglobin F is inherited independently of all the adult hemoglobin variants. These and other properties listed below divide it sharply from Hb A and its variants.

**Alkali Denaturation.** At pH 12.5 (0.04 N alkali) and at room temperature the half reaction time of denaturation ( $t_{1/2}$ ) for Hb A is 10 sec. and for Hb F is 1,000 sec.

**Ultraviolet Spectrum.** The tryptophan fine-spectrum band for Hb A is 291.0  $m\mu$  and for Hb F is 299.8  $m\mu$ .

**Electrophoresis.** The isoelectric point of Hb A is 6.87 and of Hb F is 6.95. Upon bouillon electrophoresis at pH 6.5 A and F separate. On paper electrophoresis at pH 8.0 A and F do not separate but when present in a mixture F causes lowering of the A band. Upon starch gel electrophoresis at pH 8.6 Hb F separates as a distinct band behind Hb A. With agar electro-

## Chapter 34

### The Hemoglobinopathies and Thalassemia

---

*Hermann Lehmann and J. A. M. Ager*

The observations of Pauling and his collaborators on the electrophoretic characteristics of human hemoglobins first published in 1949 form a landmark in biochemical genetics. Their observations and many which have followed have firmly established the existence of various species of human hemoglobin and have shown that a subject may have various combinations of these species circulating in his blood at the same time. The inheritance of the hemoglobins follows strict genetic patterns and certain dyscrasias of the blood may quite precisely reflect the genetic pattern of the constituent hemoglobins.

This chapter will include a review of present information on the chemical nature of the hemoglobins and the genetics of their inheritance and will attempt to classify the variant hemoglobins. In addition the diseases arising from an endowment of abnormal hemoglobin will be described and interpreted and present information regarding the nature of thalassemia discussed.

#### HUMAN HEMOGLOBIN

Hemoglobin is the principal protein of man concerned with oxygen transport. Each molecule of hemoglobin consists of one molecule of globin to which are attached four molecules of ferriprotoporphyrin IX (Fig. 34-1). This prosthetic group is common to groups of compounds concerned in redox processes in both the plant and animal kingdoms from the peroxidase of horse radish to the cytochromes of man. The protein part of the hemoglobin molecule shows a wide variation of molecular weight in the lower animals but in the vertebrates the molecular weight is relatively constant at about 68 000 (66 700 for man).

component, Hb A<sub>1</sub>, and a minor component amounting to about 3 per cent Hb A<sub>2</sub> [12]

Hemoglobin A<sub>2</sub> is a definite separate entity. It is noteworthy that it is found in the absence of Hb A<sub>1</sub> in sickle cell homozygotes. Also like Hb F it is increased in thalassemia in which Hb A<sub>1</sub> formation is decreased. Occasionally Hb A<sub>2</sub> separates into two fractions on electrophoresis A<sub>2</sub> and A<sub>2</sub>' [13-14] (Fig. 34-2). The trait A<sub>2</sub> + A<sub>2</sub>' segregates as a simple Mendelian alternative to single A<sub>2</sub>. Matings of persons with A<sub>2</sub> and A<sub>2</sub>A<sub>2</sub>' produce both types in equal proportions in the offspring.

A minute fraction on the leading edge of the A<sub>1</sub> band may also appear upon electrophoresis of normal hemoglobin. This small pointed area of hemoglobin has been designated Hb A<sub>3</sub>. Its significance is not yet clear nor is that of a small fraction of hemoglobin which may also be seen in front of the A band on chromatography at pH 6. As will be discussed later the two  $\alpha$  and two  $\beta$  polypeptide chains which together form the globin molecule differ in electrophoretic and chromatographic properties. Dissociation and recombination of these chains might take place in unequal proportions particularly at slightly acid pH. This could cause the appearance of small fractions differing from A<sub>1</sub> on electrophoresis and chromatography.

#### DIFFERENT ADULT HEMOGLOBINS

Until a few years ago interest in adult hemoglobin was centered on its prosthetic group. The heme. Carboxyhemoglobinemia, sulfhemoglobinemia, and methemoglobinemia were of clinical as well as of theoretic importance and it was known that methemoglobinemia could be either acquired or inherited. The inherited type was attributed to abnormalities in reducing systems which normally counteract the tendency toward methemoglobin formation in the red cells (cf. Chap. 33). Hörlein and Weber [15] studied a family in which the condition appeared to be associated with the hemoglobin molecule. For when globin and heme of the affected members of this family were separated and combined with normal heme and globin respectively, the abnormality went with the globin part of the respiratory pigment. Watson and her collaborators [16] had noted that the sickling phenomenon was only slight in infants and became more pronounced later when the fetal variant had been replaced by adult hemoglobin. It was the discovery of Pauling and his collaborators [17] of a second adult human hemoglobin in sickle-cell blood that became a milestone along the road of twentieth century investigative medicine. From that discovery has flowed an abundance of new light on the chemistry of human proteins, the physiology of hemoglobin, and the nature of numerous disease states of the blood. Few single papers have been the beginning of so many lines of investigation, many of them of far-reaching consequence.

chromatography' at pH 6.2 Hb F separates as a distinct band in front of Hb A.

*Chromatography* Hemoglobin F separates as a distinct band in front of Hb A on Amberlite IRC 50 at pH 8 or on carboxymethylcellulose.

*Solubility* Reduced Hb I is more soluble in phosphate buffer than is reduced Hb A.

*Amino Acid Composition* There are numerous differences. The most notable is in isoleucine content which is absent from pure Hb A and is 1.53 per cent in Hb F. The four terminal residues in Hb A are valyl only but in Hb F there are two valyl and two glycyl residues.

*Immunology* Antisera have been prepared from chickens, rabbits and other species which precipitate specifically Hb A and F respectively. Agglutinating sera have been prepared from rabbits which act on the red cells of the newborn but not on those of the adult except when the adult blood contains Hb F.

*Oxygen Dissociation* The oxygen affinity of cord blood is greater than that of adult blood. The difference disappears after dialysis against phosphate buffer.

#### HETEROGENEITY OF NORMAL ADULT HEMOGLOBIN [4-7]

Hemoglobin A is not a homogeneous protein. Derrien [10] has summarized his own experiences and that of other workers with fractional

Fig. 34.2 The heterogeneity of hemoglobin. When normal adult hemoglobin is examined by paper electrophoresis at pH 8.6 a single fraction is observed (see left unstained strip). On staining several additional minor fractions appear. These are Hb A<sub>1</sub> and A<sub>2</sub> and a nonhemoglobin component.

"salting out" of Hb A. He found six different components. Itano [11] considers these results due to the transition of soluble protein into the solid phase where the crystal forms differ at different salt concentrations. There can be no doubt that adult hemoglobin consists of at least two fractions which can easily be separated by electrophoresis, a major

gested in 1947 [26] that there might be an alternative hypothesis similar to that which had differentiated between severe and mild thalassemia in terms of their being homozygous and heterozygous states. In 1949 the same theory together with supporting evidence was put forward by Beet [27] and Neel presented conclusive proof based on numerous family studies [28].

The discovery of the sickle cell hemoglobin correlated all the data that had been accumulating. Sickling was due to an abnormal hemoglobin

Fig 34-4 The electrophoretic pattern of a sample of blood obtained from two of three of parents each of whom was a sickle-cell trait carrier. Run at pH 8.6. On the left above a sample from the father below one from the mother. On the right are samples from the elder child and the younger child.

and whereas in the heterozygous carriers of the sickle-cell trait both Hb A and Hb S were found, no A was present in patients with sickle cell anemia who were homozygous for the abnormal gene. Thus the gene for Hb A found expression in the phenotype in the presence of another for Hb S (Fig 34-4). Another hemoglobin besides S was found in small amounts in the blood of patients homozygous for sickling, but this was not Hb A. It was later shown to be Hb F persisting in these patients beyond the age of infancy [7].

Almost all the findings in sickle-cell disease can be explained by the physical properties of reduced Hb S and particularly by its low solubility. Harris [4] found that the deoxygenation of concentrated solutions of Hb S results in a semi solid gel. Under the microscope tactoids 1 to 15  $\mu$  long may be observed which are remarkably similar in shape to sickled

*Sickle cell Hemoglobin (Hemoglobin S)*

In 1910 Herrick [18] examined the blood of a severely anemic West Indian Negro student residing in Chicago and found it to contain "peculiar elongated and sickle-shaped red corpuscles." It was soon found that some Negroes had erythrocytes which appeared to be perfectly normal *in vivo*, but which could be induced to take on the sickle shape *in vitro*. Hahn and Gillespie [19] reported that sickling occurs only with low oxygen tensions and that sickled cells can revert to the normal shape

Fig. 34.3 Sick cells from the peripheral blood as they appear under low oxygen tension.

when they are exposed to sufficient oxygen (Fig. 34.3). Diggs et al. [20] distinguished between those individuals in whom the sickling of the red cells was associated with a profound disease, sickle-cell anemia, and others in whom the abnormality was a harmless trait. Sherman [31] showed that the two conditions also differ in their tendency to sickle on deoxygenation. Later it was seen that the first type of cell has a shorter life span than normal cells and that the trait cells have a normal survival time even when transfused into patients with sickle cell anemia [22, 23].

The sickling phenomenon is familial and the mode of inheritance is that of a single Mendelian dominant [24, 25]. Expression of a gene in this way in the heterozygote is now often referred to as codominance. At first it was generally assumed that the same gene produces in some persons an asymptomatic condition, the sickling trait, and in others is responsible for the severe form with anemia and other changes. Neel sug-

of two other abnormal hemoglobins. When genes for Hb A and Hb S are inherited together both hemoglobins are incorporated into the same cells. This can be concluded because in sickle cell preparations from trait carriers all cells take on the abnormal shape. However the proportion of

Fig 34.5 X-ray appearance of the skull of an adolescent patient with sickle-cell anemia. Note the thickened diploë and virtual absence of an outer table. There appears to be a ring infarct in the frontal region. (By permission of Dr W P Cockshull, University College Hospital, Ibadan, Nigeria.)

the two hemoglobins is unequal: only 20 to 40 per cent is Hb S. Accordingly the manufacture of S must proceed more slowly. That Hb A production prevails over that of S explains why sickle-cell heterozygotes carry the abnormal hemoglobin but do not suffer from the anemia.

### *Hemoglobin C*

The observation of atypical cases of sickle-cell disease with failure to find sickling in one of the two parents led to the discovery by Neel and his colleagues of a new second abnormal hemoglobin in the nonsickling parent and to the demonstration of the same pigment in the children with the intermediate type of sickle-cell disease [37-38]. In these patients hemoglobin S amounts to more than half the total hemoglobin; the con-

cells. On reoxygenation the tactoids disappear but they form again when the oxygen is removed. Perutz and his collaborators [30, 31] reported that reduced Hb S is much less soluble than reduced Hb A. Oxygenated Hb A and Hb S have the same solubility, but upon deoxygenation the solubility of Hb A falls by one half whereas that of the sickle cell hemoglobin becomes fifty times less [11]. Sickling may therefore be understood as the outcome of intracellular tactoid formation in reduced sickle cells. The greater the concentration of the reduced Hb S the more it is likely to form tactoids, and accordingly the tendency to sickle is more pronounced in sickle cell anemia than in sickle trait. The gelling of hemoglobin inside the cells increases blood viscosity. Indeed virtually all the features of the disease can be related directly or indirectly to the increase in blood viscosity which accompanies deoxygenation [32, 33]. The slower the blood flow the greater will be the deoxygenation and the more intense will be the transformation of the discoid red cell into the spoked sickled cell. These abnormally shaped cells will be phagocytized by reticuloendothelial cells; this may explain why sickle cells have a shorter life span. Should the viscous bizarre shaped cells cause blockage of small vessels a vicious circle is set up. Deoxygenation becomes more intense and the cell shape becomes more and more abnormal.

The time factor is important in the development of sickling [34]. With a normal circulation time sickle cells remain in the deoxygenated state less than the 15 sec required for sickling to begin but if for any reason they are held up in organs with a low oxygen tension there will be time for sickling. A few sickled cells are invariably found in the circulating blood in the anemia.

The clogging of small blood vessels is responsible for the "crises" of sickle cell anemia. Infarctions which can occur in any part of the body may appear as acute abdominal emergencies, pneumonia, priapism, heart disease or hematuria. Necrotic areas in the long bones arising from the closure of nutrient vessels tend to become infected and osteomyelitis is a frequent complication. A *Salmonella* osteomyelitis is almost pathognomonic of sickle cell disease. The curious x-ray appearance of the skull in Hb S disease is not fully explained (Fig. 34-5).

On the whole and for practical purposes one can assume that the sickle cell trait is harmless. However splenic infarction can occur when sickle cell trait carriers fly at high altitude in unpressurized aircraft. Severe otherwise unexplained hematuria has been seen not infrequently in patients whose only abnormality was found to be a sickle cell trait [35, 36].

The recognition of Hb S, the studies of its biochemical and physical properties and the examination of individual patients and their families went far to support the genetic theory that sickle cell anemia is a disease of the homozygote. Contradictions to this hypothesis led to the discovery

phoretic patterns of hemoglobin samples for several combinations of these hemoglobins appear in Fig. 34-6

Although Hb C trait is completely harmless the homozygous state for Hb C is definitely a disease. Under favorable conditions the hemoglobinopathy is latent but the decreased life span of the erythrocytes will exacerbate any additional stress. It is of clinical importance that sickle cell-Hb C disease and Hb C disease are associated with splenomegaly whereas in adults with sickle cell anemia the spleen cannot be felt. In sickle cell anemia numerous splenic infarcts eventually lead to autsplenectomy. The cells of Hb C disease are thin and numerous target cells can be seen (Fig. 34-7).

Since the characterization of Hb A, S, and C, numerous other human hemoglobins have been described. Their classification is complex and will be discussed in detail further on under Nomenclature of Human Hemoglobins. It may be helpful at this stage to survey what is known of the molecular changes which underlie the variations in the globin molecule.

#### THE POLYPEPTIDE CHAINS OF THE DIFFERENT HUMAN HEMOGLOBINS

Ingram's finding that the difference between hemoglobins A and S is in the amino acid sequence of the polypeptide chains forming the globin molecule resulted in an entirely new insight into the nature of protein polymorphism. The abnormality in sickle cell hemoglobin might well have been physical and could have been caused by a difference in folding of the polypeptide chains.

Indications of a difference in the free carboxylic residues had come from an ingenious differential titration by means of paper electrophoresis [41-42]. It had been calculated from the difference in isoelectric point that Hb S differs from Hb A by possessing two to four more net positive charges per molecule [17]. Scheinberg [41-42] brought forward evidence that the difference is due to a smaller free carboxylic group content in Hb A. On electrophoresis at pH 11.7 the two pigments differ in their mobility and since lysine and arginine would lose their electrical charge at pH 11.7 the difference cannot be due to one of these amino end groups. On the other hand at pH 4 and below free carboxylic groups would lose their charge and at this pH Hb A and S fail to differ on electrophoresis. From this it could be concluded that Hb S carries a smaller number of aspartic or glutamic acid residue or both. Such a difference of over all charge could have been due to an arrangement by which both globins were chemically identical but differed in the arrangements of the polypeptide chains so that fewer free carboxylic groups could influence the over all charge in hemoglobin S or it could have been due to a difference in chemical nature. Hb S possessing a lesser number of free carboxylic

sequence is that heterozygotes for these two abnormal hemoglobin genes suffer from sickle-cell disease. The anemia is modified because the total amount of Hb S in the cells is still less than that formed in the homozygous sickling condition. Thus the genetic approach had led to the discovery of a

Fig 34-6 The identification of different hemoglobins by filter paper electrophoresis. In an alkaline buffer hemoglobin will travel towards the positive pole. The speed of migration differs: adult hemoglobin (A) is faster than sickle hemoglobin (S) and S is faster than Hb C. Hb D travels at the same speed as S but can be differentiated by its inability to form a gel in the reduced state. (By permission of C. M. Edington et al. [40].)

Fig 34-7 The red cells of hemoglobin C disease as they appear in the peripheral blood.

new kind of hemoglobin under genetic control. Hemoglobin C was shown to produce a symptomless trait in heterozygotes, and its proportion in the trait-carrying parents was less than that in the children with Hb S and C. The homozygous state for hemoglobin C was not encountered by Neel, Kaplan, and Zuelzer [37], but they predicted it and it was found shortly afterwards by several other workers. Ranney and her colleagues [39] were able to show that the genes for Hb A, S, and C were allelic. Electro-

acids. Seven of these were identical in both peptides but one—the sixth—was glutamic acid in Hb A and valine in Hb S. This observation confirmed independently and indeed brilliantly the earlier predictions of Pauling [17] and Scheinberg [41–43] that the charge difference between the two proteins could be due to a loss of two carboxylic residues in Hb S, and showed that this variation was of a chemical rather than positional character. The low solubility of Hb S in its reduced state was not explained by Ingram but he pointed out that the solubility of a protein depends upon the distribution of positive and negative charges upon its surface. A change in surface charge pattern through the removal of a glutamic acid could well result in a change of solubility. Ingram's clarification of the chemical difference between the two hemoglobins also indicated for the first time just how a gene might act in the synthesis of polymorphic proteins: for the only alteration caused by the Hb S mutation was the substitution of one in 280 amino acids.

When Hb C was examined by the same methods [50] it was seen that peptide No. 4 was also affected. The Hb A No. 4 peptide had disappeared and two others had taken its place. This indicated that Hb C No. 4 peptide possesses an arginine or lysine in peptide No. 4 where Hb A and S have no bond that can be attacked by trypsin. It was then found that the glutamic acid of Hb A and the valine of Hb S are replaced by lysine in Hb C. Thus a negative charge lost in Hb S is replaced by a positive charge in Hb C. This difference explains the electrophoretic behavior of Hb C which on electrophoresis at alkaline pH (8.6) migrates behind Hb A toward the positive pole about twice as slowly as Hb S. A change from glutamic acid to lysine involves a difference of two units of electrical charge. Furthermore, these findings reinforce the genetic evidence that the two mutations occur in the same place on the gene since they affect the same amino acid. These findings are summarized in Table 34-1.

TABLE 34-1 AMINO ACID SEQUENCE IN PEPTIDE NO. 4  
H<sub>m</sub> globin  $\beta$  chain

|   |     |     |     |     |     |                  |     |     |
|---|-----|-----|-----|-----|-----|------------------|-----|-----|
| A | Val | His | Leu | Thr | Ile | Glu <sup>-</sup> | Glu | Lys |
| S | Val | His | Leu | Thr | Ile | Val              | Glu | Lys |
| C | Val | His | Leu | Tl  | Ile | Lys <sup>+</sup> | Glu | Lys |
| C | Val | His | Leu | Thr | Pro | Glu <sup>-</sup> | Gly | Lys |

Note: Val = valine; His = histidine; Leu = leucine; Tl = threonine; Pro = proline; Glu = glutamic acid; Lys = lysine; Gly = glycine.

An investigation of three samples of hemoglobin D demonstrated the fallacy of identifying a hemoglobin on the basis of its electrophoretic properties alone. This potential source of error had been recognized before and indeed Hb D had been identified as one with the electrophoretic properties of Hb S but without a tendency to cause sickling in the reduced state [11]. Two samples of Hb D which were otherwise indistinguishable—one from a Cypriot and the other from an Indian

groups. Since one molecule consists of approximately 560 amino acids, such a small difference in amino acid composition might well have been thought impossible to establish.

According to the latest estimates human hemoglobin has a molecular weight of 66,700. X-ray studies of horse hemoglobin have shown that the molecule is composed of two equal halves which together form an ellipsoid of the dimensions  $50 \times 55 \times 70 \text{ \AA}$  [43, 44]. In human hemoglobin each molecule contains four polypeptide chains of two types  $\alpha$  and  $\beta$  [45, 46]. The terminal sequence of the  $\alpha$  chains is valyl leucyl, and that of the  $\beta$  chains valyl histidyl leucyl. Since the hemoglobin molecule

Fig. 34-8. A fingerprint of the polypeptides from Hb A (right) and from Hb S (left). Electrophoresis was performed from left to right and chromatography vertically. Note that the peptides all correspond except for one indicated by the shaded area. (By permission of V. M. Ingram [47].)

consists of two identical halves it would not have been necessary to look for a difference in all the 560 amino acids but only in 260 of them, but that is still a formidable number. Ingram therefore decided to break down the molecule by tryptic digestion and to examine the smaller components separately [47, 48]. Trypsin hydrolysis breaks peptide chains where the amino acids lysine and arginine occur but nowhere else. Since there are approximately 26 molecules of lysine and arginine in each half molecule of globin, the digested protein resolves into 28 short amino acid chains (Fig. 34-8). The peptides were separated in one direction by electrophoresis and in another by chromatography on the same large sheet of paper [49]. These maps or "fingerprints" of the hemoglobin molecule split into small peptide components permitted detection of small differences between specific peptide fragments of Hb A and Hb S. Of the 28 peptide spots all but one were identical in the two fingerprints. Peptide "No. 4" occupied a different position in the fingerprint of the Hb S than of Hb A. Ingram found that this peptide contained eight amino

Hb D and in Hb E and Hb D<sub>s</sub> respectively all four hemoglobins showed individual substitutions characteristic for themselves. Yet a third hemoglobin D (D<sub>3</sub>) differed from both D and D<sub>s</sub> [52] (Fig 34 9).

Ingram now went further and determined in which of the two polypeptide chains  $\alpha$  or  $\beta$  the amino acid sequence was altered. He separated

Fig 34-10 Separation of the  $\alpha$  and  $\beta$  polypeptide chains of normal adult hemoglobin (Hb A). On the left is the fingerprint of the globin of Hb A which is composed of  $\alpha$  and  $\beta$  polypeptide chains and on the right the fingerprint of the isolated  $\beta$ -polypeptide chain. Peptides No 4 and 6 which carry the mutational characteristics of Hb S and C and I and D<sub>s</sub> respectively are part of the  $\beta$  chain. Peptide No 3 which is altered in Hb D and I is by inference in the  $\alpha$  chain. (After a sketch by Dr I. M. Ingram.)

the two chains by electrophoresis and submitted them each to fingerprinting (Fig 34 10). His results together with subsequent work with his collaborators [53-55] made it clear that peptide No 4 with the alterations for S and C and peptide No 26 with those for Hb I and D<sub>s</sub> are parts of the  $\beta$  chain and that peptide No 23 which carries the differences found in Hb I and D belongs to the  $\alpha$  chain. Thus the  $\alpha$  chains of hemoglobins A, S, C and I are all identical and normal and the  $\beta$  chains of hemoglobins A, I and D are all identical and normal.

This work found full confirmation from some ingenious hybridiza-

Fig. 34-9 The peptides of three samples of Hb D  $\alpha$   $\beta$  and  $\gamma$ . All three samples were indistinguishable on electrophoresis and chromatography. The fingerprints however were different in all three. The illustration shows schematically the results of staining the fingerprints with ninhydrin and specifically for histidine, arginine and tyrosine residues respectively. (By permission of H. L. Itano [1].)

showed a chemical difference in certain peptides. Some time later when hemoglobins L and I were examined it was found that the change in the first hemoglobin D ( $D_a$ ) was found in the same peptide which was altered in hemoglobin I. In the second ( $D_\beta$ ) there was a difference from Hb A in amino acid composition of the same peptide which is altered in hemoglobin E. Although the same peptide was changed in Hb I and

possess four genes: a normal  $\beta$  chain gene and abnormal  $\alpha$ -chain gene responsible for the Hb P and an abnormal  $\beta$  chain gene and a normal  $\alpha$  chain gene responsible for Hb S. He could then form his three adult hemoglobins A, S, and P as follows:

|   |      |
|---|------|
| Normal $\alpha$ chain gene + normal $\beta$ -chain gene   | Hb A |
| Abnormal $\alpha$ chain gene + normal $\beta$ chain gene  | Hb P |
| Normal $\alpha$ chain gene + abnormal $\beta$ -chain gene | Hb S |

There was in this case no combination of the two abnormal  $\alpha$  and  $\beta$  chains. Indeed experiments designed to produce such a hybrid *in vitro*

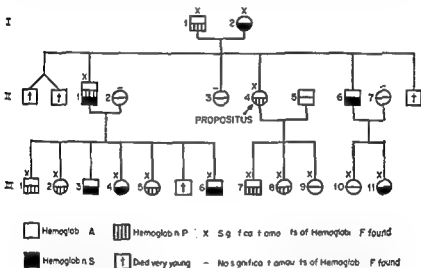

Fig 34 11 The appearance of hemoglobins A, S, and P in one family from the Belgian Congo. The son of a Hb A + S father and an A + S mother had Hb A, S, and P. He married a woman with no abnormal hemoglobins and had by her lot of Hb A + S and Hb A + S offspring. This inheritance pattern supports the theory of two adult hemoglobin genes for man. One determines the  $\alpha$  chain and the other the  $\beta$  chain (By permission of E. W. S. with et al [61]).

were not successful. On the other hand, hybrids could be formed between the non- $\alpha$  chain of Hb I and the  $\alpha$  chain of Hb I using the hemoglobin of another member of this family [63] (Fig 34 12).

With one exception, Ingram's theory has stood the test of what was known before and what has been discovered since. In a case of Hb G, which in this study came from an American family with Italian origins [64] and was probably not identical with the West African Hb G of Fodington and Lehmann [66], the  $\beta$  chain was found to be abnormal [67]. If this is true, it could not be understood on Ingram's theory that the genes for Hb S and his Hb C are nonallelic, as suggested by Neel [60]. A close

tion" experiments carried out respectively by Itano and Schroeder and their collaborators Singer and Itano [56] had observed that human hemoglobin dissociates at pH 4.3 into two unequal halves. One might have expected to find the two symmetric half molecules which had been recognized in x-ray studies each consisting of one  $\alpha$  and one  $\beta$  chain  $\alpha\beta$  and  $\alpha\beta$ . However, at acid pH the two halves which were obtained were asymmetric and consisted of the two  $\alpha$  chains and the two  $\beta$  chains respectively  $\alpha_2$  and  $\beta_2$ . When mixtures of Hb A and Hb S [56, 57] were submitted to this dissociation of the chains and when these were then recombined by changing the pH from acid to alkaline, the subunits of the globin molecule combined indiscriminately. The  $\alpha$  chains from Hb A ( $\alpha_1^A$ ) combined both with the  $\beta$  chains from Hb A ( $\beta_1^A$ ) and from Hb S ( $\beta_1^S$ ) and vice versa. Of the four possible combinations only those with the  $\beta$  chains of Hb S had the properties of sickle-cell hemoglobin regardless of whether the  $\alpha$  chains were derived from Hb A or Hb S. Thus both from Ingram's direct analysis and from the hybridization studies, it may be concluded that the  $\alpha$  chains of Hb A and Hb S are interchangeable. A logical next step was to attempt hybridization of an abnormal  $\alpha$  chain with an abnormal  $\beta$  chain in order to see whether this would result in a new and hitherto unobserved hemoglobin. Itano succeeded in preparing such pigments by dissociating and recombining mixtures of hemoglobins I<sup>S</sup> and C [58] and was even able to combine the asymmetric subunits of human and canine hemoglobin molecules producing thereby two new hemoglobins [59].

Ingram [53] proposed a new genetic interpretation of the inheritance of human hemoglobin on the basis of these findings. The possibility that there might be two hemoglobin genes had been put forward by Neel on the basis of a family study in which it was concluded that the genes for Hb S and G cannot be alleles [60]. Smith and Torbert [61] found in a single individual Hb A and S, and a 'fast' hemoglobin. Similarly Cabannes and Portier [62] found a family where Hb D and H were inherited independently and together with Hb A. Dherte, Lehmann and Vandepitte [63] observed a man who possessed hemoglobins S, P and A and who on marrying a normal wife had children with the traits for both Hb S and Hb P. Another individual with Hb A<sup>S</sup> and P was examined independently, but no family study could be carried out [64] (Fig. 34.11). Ingram suggested that the two hemoglobin genes might correspond to the two peptide chains of human globin, one determining the  $\alpha$  chain and the other the  $\beta$  chain. The alterations in hemoglobins S, C, D<sub>s</sub> and E would then be the outcome of mutations in the  $\beta$  chain gene and those seen in D<sup>I</sup> and presumably P would be caused by mutations in the  $\alpha$  chain gene. One could then readily understand why the son of a marriage of a sickle cell trait carrier with a Hb P trait carrier should possess three hemoglobins (cf. Fig. 34.11). If he inherited Hb P and S he would

fundamental difference between adult hemoglobins and Hb F. Schroeder and Matsuda [70] found that in addition to terminal valyl residues, Hb F contains chains with glycyl residues ( $\gamma$  chain). The valyl chain is in fact the  $\alpha$  chain of normal adult hemoglobin (valyl leucyl) [71]. It can now be understood why there are such profound differences between the adult hemoglobins and Hb F. These differences extend to a shift in the position of the tryptophan fine spectrum band and to altered immunologic properties. Unlike Hb A and S, for example, Hb A and F do not differ by two amino acids per molecule, but rather one-half of each is composed of an entirely different polypeptide complex. Certain differences in products of tryptic digestion of Hb A and F have also been observed by Katz and Chernoff [72]. They observed 19 of 30 possible peptides and found that 11 of these were the same in Hb A and Hb F. An abnormal fetal hemoglobin, first seen at St. Bartholomew's Hospital in London and called hemoglobin Barts [73], was found to be the exact fetal equivalent of Hb H [74]. It consisted entirely of the glycyl chains of hemoglobin F in the form of a tetramer. Hemoglobin H ( $\beta_4$ ) may be found without Hb Barts ( $\gamma_4$ ) and vice versa, but a family has been studied in which the mother and one of her four children had Hb A, H Barts, and F [75]. More Hb Barts was present than Hb H, and whereas Hb A amounted to more than 80 per cent of the total, Hb F was found only in traces. This suggests that if there is a shortage of  $\alpha$  chains, less would be attached to  $\gamma$  chains than to  $\beta$  chains.

On the basis of what is known of the polypeptide chains and their amino acid sequences, one can now classify hemoglobins into those which possess an  $\alpha$  chain and those which do not. Those which do not are Hb H and Barts. Alpha chain hemoglobins can then be subdivided into those with and without a  $\beta$  chain. Those with a  $\beta$  chain are all the hitherto examined adult hemoglobins (except Hb H) and that without a  $\beta$  chain is Hb F ( $\alpha_2\gamma_2$ ). The  $\alpha\beta_2$  hemoglobins can be subdivided into normal adult hemoglobin and two other groups: the first carrying a mutational alteration in the  $\alpha$  chain (D, I, P, Q) and the second with mutational alterations in the  $\beta$  chain (S, C, D $\beta$ , E, G, J, L, and V). Responsible genes would be the following:  $\alpha$  chain gene,  $\beta$  chain gene,  $\gamma$  chain gene, and at least one gene concerned with the amount of  $\alpha$  chains to be produced. This gene or another would also control the allocation of the  $\alpha$  chains to either  $\beta$  or  $\gamma$  chains.

## NOMENCLATURE OF HUMAN HEMOGLOBINS

It is clear that the time will come when hemoglobins will be classified and named according to their polypeptide chains and the amino acid sequences they contain. Meanwhile, a more empirical nomenclature will have to be used. The position is not unlike that of the blood groups.

examination of the experimental evidence for this non allelism [65] suggests that this problem requires a careful study.

On the basis of Ingram's theory it should be comparatively easy to determine whether an abnormal hemoglobin is due to an  $\alpha$  chain or a  $\beta$  chain mutation. A fingerprint would show whether the alteration occurs in a peptide belonging to one of the two chains. Further, hybridization with Hb S or C ( $\beta$  chain mutation) would result in a new abnormal hybrid if the hemoglobin under test is the outcome of an  $\alpha$  chain mutation and hybridization with Hb D<sub>e</sub> or I ( $\alpha$ -chain mutation) similarly.

Fig 34-1. A hemoglobin hybrid. The propositus of the family illustrated in Fig 34-11 possesses Hb A ( $\alpha_2\beta_2$ ), Hb I ( $\alpha^F\beta_2$ ), and Hb F ( $\alpha_2\gamma_2$ ). On dissociation of the peptide chains at pH 4.6 and recombination at pH 8.6, a new hemoglobin can be seen on electrophoresis, presumably  $\alpha^F\gamma_2$ . On the right is a hemoglobin A + S control. (By permission of E. W. Smith et al. [61].)

would give a new abnormal hybrid if the test hemoglobin is the result of a  $\beta$ -chain mutation. Such experiments have by now been carried out with Hb I, N, I, O, K, Norfolk, and Q and have indicated that the first four must carry their abnormality of amino acid sequence in the  $\beta$  chain, the others belong to the hemoglobins with abnormal  $\alpha$  chains [155].

Yet another type of abnormality has been established in the case of Hb H. It differs from the other adult hemoglobins in that it is absent from the blood of parents of persons with Hb H, but it is occasionally found in a sibling, or grandparent. It does not seem to appear unless a gene for thalassemia is also present [63]. Jones et al. [69] have recently reported that Hb H consists entirely of normal  $\beta$  chains. Since its molecular weight does not differ from that of Hb A, the  $\beta$  chains must be associated in a tetramer.

Investigation of the polypeptide chains has also thrown light on the

All the hemoglobins (with the possible exception of hemoglobin M) have been discovered because they showed electrophoretic properties different from hemoglobin A. It must be expected that there are many more in which substitutions in the peptide chains do not alter their electric charge and also that there may be hemoglobins with identical electrophoretic properties which do not have the identical amino acid sequence. Indeed this has already been shown for Hb D for when other wise identical samples were submitted to an analysis of their peptides after tryptic digestion [52] sequence differences were observed. Electrophoretic differences are often small and it has been suggested that some

Fig 34-13 Separation by resin chromatography (Amberlite IRC 50 pH 6) of hemoglobins which on electrophoresis at pH 8.6 move similarly or identically. In this instance chromatography was used to identify an unknown hemoglobin C36% as Hb G. The order of electrophoretic mobility at pH 8.6: A Q G L = P D is on chromatography A = P G D Q L. Hb P and Hb A form a broad band. (By permission of J. A. Hunt [14].)

of the electrophoretically abnormal variants might be artifacts [89] but when the variants occur in families the evidence is convincing for a new type of hemoglobin. Electrophoresis at varying pH and chromatography on Amberlite IRC 50 [94] have been useful in differentiating hemoglobins which have closely similar electrophoretic properties at alkaline pH. A chromatographic comparison of several hemoglobins appears in Fig 34-13.

Ager, Lehmann and Vella [89] have proposed the following classification as a temporary solution. They divided the human hemoglobins into two major groups: fetal and adult. The fetal group, which shows an ultraviolet spectrum of the fetal type, includes Hb F, the pigment of Fetus and Papaspyrou [95]  $\gamma_4$  (Barts) and Alexandra. The adult variants are divided into six groups according to their behavior on paper electrophoresis at alkaline pH. These groups can be established by using as markers normal hemoglobin and Hb  $\beta_4$  (H) and S. Erythrocytes containing Hb  $\beta_4$  can be identified independently of electrophoretic methods because cells containing this hemoglobin form inclusion bodies upon

Although much information has been gained about the chemical nature of the agglutinogens A and B, the H substance and the Lewis substance which coats the red cells blood groups are still identified according to their agglutinins

In 1953 Chernoff and his colleagues [76] proposed that for mnemonic reasons the following letters be assigned to hemoglobin known at the time

- F Fetal hemoglobin
- A Normal adult hemoglobin
- S Sick cell hemoglobin

Later Singer [77] proposed that the letter M should be used for the abnormal methemoglobin of Horlein and Weber [16]. All other hemoglobins which might be discovered later were to be known by letters of the alphabet in the order of their discovery beginning with the letter C (b or B had at one time been used for the sickle cell hemoglobin). Difficulties arose when different hemoglobins were given the same letter by their discoverers or when two or more designations were suggested for the same hemoglobin. Thus hemoglobin A<sub>2</sub>' is still being called A<sub>2</sub> by some investigators [14] and B<sub>2</sub> by others [78]. It is doubtful whether Hb G discovered in West Africa [66] is the same as Hb G discovered by Schwartz and his colleagues [65]. Cabannes and Buhr [79] named a 'fast' hemoglobin discovered by them in Algeria Hb I not knowing that this letter had been allotted by Rucknagel and his colleagues [80] to a hemoglobin which they had originally named Hb H [91]. Rucknagel and coworkers had not been aware that the letter H had been given to a newly discovered hemoglobin still known by this letter today [82]. Cabannes et al [83] altered their designation from I to J, but then found that this letter had been given to another newly discovered hemoglobin [84]. Eventually it was decided at the Sixth Congress of the International Society for Hematology to rename this hemoglobin for a third time and it has since been known as Hb K [85]. In 1956 Robinson et al [86] suggested a way out of this dilemma by naming two hemoglobins 'Liberian I' and 'Liberian II' after the place where they had been discovered. Later these were designated Hb N and K [73]. In this way Hb P was first known as the 'Galveston' type [87] and Hb O as 'Buginese' [88]. Hopkins I' and 'Hopkins II' seen at Johns Hopkins Hospital in Baltimore [61] are presumably hemoglobins I and J. Hemoglobin Norfolk [89], hemoglobin Sud Vietnam [90] and Stanleyville I and 'Stanleyville II' [91] are other examples. Two abnormal fetal hemoglobins have been named after the hospitals where they were first seen: Bart's after St Bartholomew's Hospital in London [73] and Alexandra after the hospital of that name in Athens [92]. For Bart's the designation of γ<sub>4</sub> will have to be used in the future [74].

and well known hemoglobins by their present names S C D F etc but the more obscure pigments might well be labeled by giving them a group number or letter followed by a small letter. If after such a scheme was adopted a hemoglobin was found which moved for example between hemoglobins E A<sub>2</sub> on the one hand and hemoglobin O on the other (C group 3a and 3b and C group 4) it would be classified as C group 3<sub>4</sub>. If one wished to place a hemoglobin between the hypothetical pigment C group 3<sub>4</sub>' and O (C group 4) it could be designated C group 3<sub>4</sub>//4.

## VARIANTS OF FETAL HEMOGLOBIN

### PRE-FETAL HEMOGLOBIN

It has been claimed that just as Hb F precedes Hb A in human development so another more primitive hemoglobin precedes Hb F in the fetus. There is no evidence that Hb F precedes the adult pigment in the true sense of the word for although the proportion of Hb I is higher in the embryo than at birth Hb A has been found in the youngest embryos examined.

There is evidence both in favor of and against the existence of a pre-fetal primitive hemoglobin. Allison's primitive hemoglobin P [97] was not a human hemoglobin but was found in rat embryos [98]. In man investigation is difficult because of the small amount of blood which can be obtained from embryos when they become available. Halbrecht and Klubanski [99-100] found in embryos an alkali resistant hemoglobin with a lower mobility on paper electrophoresis at pH 8.6 than that of either Hb F or A. Kunzer and Drescher [101-103] also found a primitive alkali resistant hemoglobin with an ultraviolet spectrum of the Hb I type. Other workers have failed to find either in embryonic or cord blood any hemoglobin other than A and I [104-106].

### HETEROGENEITY OF FETAL HEMOGLOBIN

Vella [107] found in addition to a principal fraction two small components of hemoglobin in cord blood. Since his observations were made by paper electrophoresis it cannot be said at present in which way they are related to minor fractions observed on chromatography [94-108-110]. Indeed chromatographic results are not entirely consistent among themselves. Vella considers the two small fractions the same as those seen by him and others on occasion in greater quantity and described as abnormal fetal hemoglobin. One is the fast moving pigment of Lessas and Lapayrou [91] and the other hemoglobin Alexandra [92]. Thus Hb I would appear to be heterogeneous just as is Hb A where in addition to the main component there are smaller fractions A<sub>2</sub> and A<sub>1</sub>. Traces of Hb Alexandra can be found in all cord bloods but an increased

incubation with cresyl blue. The electrophoretic properties are summarized in Fig. 31.14. Sickle cells can almost readily be identified upon incubation under reducing conditions. Hemoglobin A is identified as that occurring in a number of normal controls. With the help of Hb A $\beta_4$  (H) and S six groups of adult hemoglobins can be established. These

Fig. 31.14. A diagram showing the pattern of adult hemoglobins on paper electrophoresis at pH 8.6. (By permission of A. L. Ogden et al. and the Honorary Editors of the *Proceedings of the Royal Society of Medicine* [98].)

may be numbered I, II, III, etc. or they may be given the name of the first hemoglobin discovered within the group.

|           |                                       |         |
|-----------|---------------------------------------|---------|
| Group I   | Hemoglobins moving more slowly than S | C group |
| Group II  | Hemoglobins moving like S             | S group |
| Group III | Hemoglobins moving between S and A    | G group |
| Group IV  | Hemoglobins moving like A             | A group |
| Group V   | Hemoglobins moving between A and H    | J group |
| Group VI  | Hemoglobins moving like H             | H group |

Within these six groups hemoglobins could again be numbered according to their mobility or when they have the same mobility they could be given (according to the time of their discovery) the additional letters a, b, c, etc.

When such a scheme is accepted a newly discovered hemoglobin could then be allotted to one of the six groups. Clearly a digit should be assigned only after full comparison and international agreement. It is obvious that it would remain the general practice to refer to the common

3 *Hemoglobin Bart's* ( $\gamma_4$ ) On electrophoresis at pH 8.6 this hemoglobin [73-74] moves faster than J and more slowly than H similarly to Hb N. On chromatography at pH 6 it moves fastest of all known hemoglobins. It was thought to be an abnormal fetal hemoglobin because of its absence in both parents because of its resistance to alkali denaturation (intermediate between those of Hb A and Hb F) and because of its ultraviolet spectrum which was of the Hb F type. Hemoglobin Bart's disappears as the child grows older. It has been seen in approximately 50 cord bloods in various parts of the world.

There are now also records of Hb Bart's in an older child and in adults. The first was a Creek boy with thalassemia [112]. The two adults were

Fig. 34-15. The Papanispyrou abnormal hemoglobin. Paper electrophoresis at pH 8.6. On the left, cord blood; and on the right, Hb A and J. The fast-moving hemoglobin in the cord blood moves similarly to Hb J. Its ultraviolet spectrum is of the Hb F type.

a Jewess from Baghdad and her daughter [75]. In these patients Hb Bart's ( $\gamma_4$ ) was found together with Hb H ( $\beta_4$ ) so that these two women exhibited a dual  $\alpha$  chain deficiency in adult and fetal hemoglobin. One might expect such a dual deficiency to occur more often and there are indications that this might indeed be the case. Huisman [115] found that Hb H resembles Hb F in amino acid composition, particularly in its high isoleucine content (A 0.03 per cent, F 1.85 per cent, and H 1.2 per cent). Since the  $\alpha$  chains of Hb F and Hb A are identical, one may presume that the higher isoleucine content of Hb F is due to its  $\gamma$  chain. Since Hb H is now known to be the tetramer of the  $\beta$  chain [69], Huisman's observation is difficult to understand. His isolation of Hb H was by electrophoresis on a starch slab, a method in which Hb Bart's at the time not yet described might well fuse into Hb H. If Huisman's preparation of Hb H also contained an undetected admixture of Hb Bart's, he would have found a fetal type of amino acid composition in his analysis. A report from Thailand [116] mentions two fast hemoglobin components found in thalassemia hemoglobin H disease and states that the second component resembles Hb Bart's, but the details have not yet appeared.

amount would be considered an abnormality just as an increased Hb A<sub>2</sub> is considered abnormal

### ABNORMAL FETAL HEMOGLOBINS

Fessas and Papaspyrou [91] observed in an infant a fast moving hemoglobin which disappeared as the child grew older. This pigment was described as moving at alkaline pH on paper electrophoresis between A and J. At the same time Vella observed a hemoglobin in cord blood which was sent to Athens and considered by Fessas to be identical with the pigment he had described. This hemoglobin was then referred to as the hemoglobin of Fessas and Papaspyrou in order to differentiate it from another faster moving fetal hemoglobin Hb Bart's. Recently Fessas has observed more examples of a fast hemoglobin in cord blood and although a comparison with his original specimen is no longer possible he now considers that this hemoglobin was in fact identical with Hb Bart's and not with the hemoglobin seen in Singapore by Vella [107]. The designation of a hemoglobin which unlike Hb Bart's moves more slowly than Hb J on electrophoresis at pH 8.6 as "hemoglobin of Fessas and Papaspyrou" may therefore have to be abandoned. The question of renaming Hb Bart's does not need to arise since this has now been identified as the  $\gamma_2$  hemoglobin (i.e. a tetramer of  $\gamma$  chains) and it will probably be referred to as such in the future [74].

Three hemoglobins other than  $\Gamma$  are thus known which exhibit features similar to those of Hb F. The first two may possibly be present in normal cord blood but only in low quantity.

1 *Hemoglobin of Fessas and Papaspyrou* [95-107] This is the least well-defined abnormal fetal hemoglobin. On paper electrophoresis at pH 8.6 it moves faster than Hb A but more slowly than Hb J and on chromatography at pH 6 it moves between Hb  $\Gamma$  and H. The ultraviolet spectrum is of Hb  $\Gamma$  type. Investigators either have not found it to be alkali resistant [95] or have not examined it for alkali resistance [107-112]. Recent observations have been made in Indonesia [113] and in Nigeria [114].

2 *Hemoglobin Alexandra* [92] This hemoglobin moves on paper electrophoresis at alkaline pH more slowly than Hb S and faster than Hb C, i.e. it is similar to the Hb O (Fig. 34.15-34.16). Unlike Hb O it behaves chromatographically on agar electrophoresis at pH 6 like Hb F, and moves faster than Hb A. The ultraviolet spectrum is of the Hb F type. It is more resistant to alkali denaturation than Hb A.

This hemoglobin has been described twice: once in a Greek and once in a Chinese infant. If there should be a connection between the observations of a slow moving prefetal hemoglobin [99] and the so-called abnormal fetal hemoglobins it is most likely that this would relate to Hb Alexandra.

Gamma<sub>4</sub> hemoglobin was originally discovered in an infant of mixed Caucasian Negro Chinese extraction. The second child observed in Britain was also of West Indian origin and the parents showed both Negroid and Mongoloid features [117]. Further instances were seen in a sample of cord blood from Nigeria [114] and in one from a Negro infant from Texas [118]. Two cases of  $\gamma_4$  were observed in Chinese infants in Singapore [107]. In Thailand 22 of 415 cord bloods contained this abnormal fetal component (two were twins) [116]. It was in this study that

Fig 34-17 Two fast moving gel normal fetal hemoglobin gels. On the left is the hemoglobin of Fessas and Papaspyrou and on the right hemoglobin Bart's. Paper electrophoresis at pH 8.6.

evidence for a possible association between the two  $\alpha$  chain deficiencies was presented, but the authors also record that they have seen one infant with only one  $\gamma_4$ , whereas a sister showed only the other  $\beta_4$ .

Most of the cases of  $\beta_4$  have been recorded in Chinese and in Greeks. It is remarkable that the same association occurs both for Hb Alexandra and for  $\gamma_4$ . The only Caucasians with  $\gamma_4$  so far seen have been Greeks. In addition to the Greek boy with thalassemia already mentioned [112] Fessas [119] states that he has seen numerous instances of this hemoglobin in Athens and indeed as stated above considers that his first report [9] of an abnormal fetal hemoglobin was one of  $\gamma_4$  rather than of the other fast abnormal fetal hemoglobin which has hitherto been referred to as the Fessas and Papaspyrou component (Figs 34-17, 34-18).

## ADULT HEMOGLOBINS

### Highly Occurring Variants 1 S C D I

Hemoglobin 1 is the normal adult hemoglobin. Its own peculiar abnormality is thalassemia, which is the outcome of a reduced ability to form Hb A and does not relate to any of the other hemoglobins. It is of course possible that what is now considered to be a single hemoglobin A

Fig 34-16 Hemoglobin Alexandra moves on electrophoresis at pH 8.6 exactly like hemoglobin O<sub>1c</sub> between S and III (or V). It can be differentiated from hemoglobin O by chromatography at pH 6 and on agar electrophoresis at pH 6.2. By these two methods it shows a greater mobility than V, whereas O moves behind V. In addition Alexandra has a fetal type of ultraviolet spectrum. (By permission of J. A. M. Ager et al [89].)

mia [123] until with the introduction of electrophoretic technique some for example were found to be Hb C disease [123]. Thus whether there is a deficiency of Hb A *per se* as in thalassemia or whether Hb A has been replaced by another hemoglobin the resulting clinical pictures are remarkably alike. An exception of course is sickle-cell disease with its additional complications due to intravascular infarcts. There is other evidence suggesting that a deficiency of Hb A rather than the presence of other hemoglobins causes microcytosis. Whereas trait carriers are asymptomatic double heterozygotes for an abnormal hemoglobin and for

Fig 34 13 Sickle cell trait and sickle-cell thalassemia. The sample on the left shows the sickle-cell trait and that on the right the hemoglobin of a double heterozygote for Hb S and thalassemia respectively. Hb A formation is suppressed when thalassemia is present.

thalassemia (in whom the proportion of Hb A is lower than in simple abnormal hemoglobin trait carriers) resemble clinically homozygotes for the appropriate abnormal hemoglobin. Thus in the case of sickle cell trait they present with sickle-cell thalassemia disease [124-132] and in that of hemoglobin C trait with hemoglobin C thalassemia [133-134] (Fig 34 19). The clinical condition approaches that of the homozygous state more nearly when the relative concentration of the abnormal hemoglobin is higher. This rule is not universal. Hemoglobin F disease tends to be milder than the combination of Hb I trait with thalassemia [135-139]. This is true even though in Hb F thalassemia more commonly than in any other of the doubly heterozygous conditions the suppression of Hb A production is complete. In an Indian family where Hb J and thalassemia were found [140] a double heterozygote showed no suppression of Hb A formation and the proportion of A to J was the

could be a group of different hemoglobins with single amino acid substitutions which do not affect electrophoretic mobility. Ingram et al have in fact suggested that the hemoglobin A in thalassemia might be an abnormal hemoglobin of this type, and that there might be  $\alpha$  chain substituted and  $\beta$  chain substituted hemoglobins A' [170]. This is not impossible because it is known that otherwise indistinguishable samples of hemoglobin D possess different amino acid sequences [59]. The abnormality in thalassemia would be in A<sub>1</sub> the main component. If Ingram's theory of an abnormal hemoglobin indistinguishable at present from Hb A is confirmed then thalassemia minor would be an example of a disability due to an abnormal hemoglobin inherited together with

Fig 34-18 A dual  $\alpha$ -chain deficiency. Comparison by paper electrophoresis at pH 8.6 of a sample containing Hb A and H with one from a woman with Hb A F (trace) Bart's and H. These hemoglobins may alternately be referred to as  $\alpha_1\beta_2$ ,  $\alpha_2$  (trace)  $\gamma$  and  $\beta_4$ . (By permission of I. M. Katz et al [72].)

normal Hb A. With certain qualifications for the sickle cell trait the concept holds at the present time that a trait for an abnormal hemoglobin is harmless.

With one exception the homozygous state for Hb G [121] all homozygotes for one abnormal hemoglobin gene and all double heterozygotes for two different abnormal genes have clinical manifestations of the abnormality. It seems that the absence of Hb A is associated with a flattened cell and a low mean cell hemoglobin content. The abnormality results in a decreased osmotic fragility because the resistance of a red cell to hydration is largely a measure of the difference between the volume of the cell and that of a sphere of equal surface [122]. There is invariably a shortened life span although this investigation has not yet been carried out in all these disorders with equal thoroughness. It may be assumed that this abnormality which is common to all these conditions has a common denominator the absence or shortage of Hb A. It is noteworthy that in thalassemia in which (as it may still be assumed) Hb A is the only adult hemoglobin the pathologic picture is much the same as in the hemoglobinopathies due to abnormal hemoglobins. A number of homozygous conditions were in fact thought to be instances of thalassemia.

tion in the No 4 peptide of the fingerprint the alteration in Hb E occurs in the No 26 peptide (Fig 34 21) The amino acid change explains its electrophoretic mobility at pH 8.6 but not its behavior at pH 6.5. One might conclude that the position of an amino acid substitution in the molecule would influence the electrophoretic behavior as well as the

Fig 34 21 A summary of the mutational changes as seen in the peptide fingerprint of Hb S and E (By permission of S H Lee et al [9])

Fig 34 22 The inheritance pattern in a family with Hb A, S, and E. For further locus, see text (By permission of the British Medical Journal [1958])

change in electrical charge. Hemoglobin S and C, which have their amino acid substitution in the same amino acid link of the  $\beta$  chain, are allelic characters [39]. There is only one record of a family in which Hb S and E occurred together [146]. There was conflicting evidence as regards the inheritance of the two hemoglobins (Fig 34 22). The son of a woman with hemoglobins S and E presented the same hemoglobin combination. The father had died. This finding would exclude that the genes for Hb S and E are alleles only if the father had been proved not

same as in persons with nonthalassemic Hb J trait. There was also no evidence of a hemoglobinopathy ("hemoglobin J thal. emia") in this person.

*Hemoglobin D* was first found in a patient with atypical hemolytic anemia. Electrophoresis revealed a single hemoglobin migrating in the position of Hb S [141, 142]. One of the parents failed to show sickle cells on repeated tests, but on electrophoresis a sickle-cell trait pattern was found. It was then discovered that a hemoglobin with the electrophoretic

Fig. 34-20. A comparison of Hb C and Hb E tracts. Hb E moves slightly faster than Hb C. Paper electrophoresis at pH 8.6.

properties of Hb S but without its abnormally low solubility in the reduced state was responsible for the conflicting observations. The propositus was in fact suffering not from sickle-cell anemia but from sickle-cell-hemoglobin D disease. The parent was a Hb D trait carrier. At one time thought to be a rare hemoglobin, D is now known to occur in 2 per cent of Punjabis and in 1 per cent of Lohana speaking Gujaratis in southern India [143]. It is now known that "hemoglobin D" is not a single compound but that in this electrophoretically and otherwise identical group several pigments with identical charge but different peptide sequence are included [142].

*Hemoglobin E* was discovered in a family in California [144] and independently in Thailand [135, 145]. The observations in Thailand provided the first evidence that abnormal hemoglobins other than Hb S exist at high frequency in non-Negroids. On electrophoresis at alkaline pH, Hb E is very similar to Hb C, but unlike C it is similar to Hb S on electrophoresis at acid pH (Fig. 34-20). The mutational change in Hb E is in the  $\beta$  chain and as in Hb C involves the substitution of a glutamyl residue of Hb A by a lysyl residue. The peptide affected is, however, not the same in both cases. Whereas for Hb C (and S) there is an altera-

[148] This subject is discussed fully in Chap 33. The variants are named after the localities where they were found  $M_{H(nion)}$ ,  $M_{H(sakatoon)}$ ,  $M_{H(nyctal)$ . Inheritance follows simple Mendelian rules and the affected individuals are thought to be heterozygotes.

*Hemoglobin H* is now known to be  $\beta_4$ . This deficiency of the alpha chain does not become apparent unless there is also a gene for thalassemia [68]. The hemoglobin was discovered in 1933 in a Chinese family [62] and also

Fig. 34-23. Inclusion bodies in cells containing Hb H. The cells were incubated at 37°C with isotonic cresyl blue. The large inclusions which give the cells almost a nucleated appearance are giant inclusions seen in patients after splenectomy.

in Greece [149]. It has little stability and denatures on storage in the cold. On incubation with cresyl blue, red cells containing this hemoglobin form numerous blue inclusion bodies (Fig. 34-23). These probably represent small foci of denatured hemoglobin.

On paper electrophoresis at pH 8.6, Hb H and I are the fastest moving pigments. At pH 8.0, Hb H is the only known hemoglobin which migrates toward the anode.

*The Lepore hemoglobin* (named after the family in which it was discovered) [150] was found during family studies of cases with thalassemia major. No other examples outside this family have yet been reported. Both parents were of Italian extraction. The propositus, an infant ap-

to carry the sickle cell trait, and about one fifth of the population to which this family belonged are sickle cell trait carriers. On the other hand, in the next generation four children of the man with the two abnormal hemoglobins and of his normal wife had only one abnormal hemoglobin each. Thus on the whole the evidence favors allelism or close linkage of the genes for Hb E and S. Hunt and Ingram [147] state that the locus of the Hb E mutation is probably some distance away from that of the Hb S locus in the gene of hemoglobin. Nevertheless they may be closely linked in the usually accepted genetic sense. The specific chain alterations of Hb A and E are as follows:

Hb A—Val Asp Val Asp Glu Val Gly Gly Glu Ala Leu Gly Arg  
 Hb E—Val Asp Val Asp Glu Val Gly Gly Lys Ala Leu Gly Arg

The known combinations of Hb S, C, D and E appear in Table 34-2.

TABLE 34-2 KNOWN COMBINATIONS OF HEMOGLOBINS S, C, D AND E

| Disease or trait                    | Genotypes | Hemoglobins found |
|-------------------------------------|-----------|-------------------|
| Asymptomatic traits                 |           |                   |
| Sickle-cell trait                   | AS        | A + S             |
| Sickle-cell hemoglobin C trait      | CS        | C + S             |
| Hemoglobin C trait                  | AC        | A + C             |
| Hemoglobin D trait                  | AD        | A + D             |
| Hemoglobin E trait                  | AE        | A + E             |
| Sickle-cell hemoglobin J trait      | JS        | S + A + P + (F)   |
| Sickle-cell diseases                |           |                   |
| Classical sickle-cell anemia        | SS        | E + F             |
| Sickle-cell thalassemia             | AS + thal | S + A + F         |
| Sickle-cell hemoglobin C disease    | SC        | S + C + (F)       |
| Sickle-cell hemoglobin D disease    | SD        | S + D             |
| Sickle-cell hemoglobin E disease    | SE        | S + E             |
| Sickle-cell hemoglobin J disease    | SJ        | S + J             |
| Sickle-cell hemoglobin N disease    | SN        | S + N             |
| Thalassemias                        |           |                   |
| Sickle-cell thalassemia             | AS + thal | S + A + F         |
| Hb C thalassemia                    | AC + thal | C + A + (F)       |
| Hb D thalassemia                    | AD + thal | D + F             |
| Hb E thalassemia                    | AE + thal | E + F             |
| Nonsickling nonthalassemic diseases |           |                   |
| Hemoglobin C disease                | CC        | C + (F)           |
| Hemoglobin D disease                | DD        | D                 |

Note: (F) = F irregularly found

### *Hemoglobins Associated with a Hemoglobinopathy in the Heterozygote*

Hemoglobin M originally described in 1948 [15] is now known to occur in three variants all distinguished by their spectrum in the visible region

*Hemoglobin Q* was seen in a Chinese family [158]. The first patient also had Hb II. In this patient who suffered from a thalassemia like condition Hb Q replaced the A which is usually seen with Hb II. The only other person observed was the mother of the propositus who showed a hemoglobin mixture of 60 per cent Hb A and 40 per cent Hb Q. The mutational change in Hb Q is in the  $\alpha$  chain. Hb Q moves on electrophoresis at pH 8.6 just faster than Hb G and is again best differentiated from similar slow hemoglobins by chromatography at pH 6 (cf Fig. 34.13).

Fig. 34.14 Hemoglobin G on paper electrophoresis at pH 8.6. Hb G moves faster than S and D but separates clearly from Hb A.

*Stanleyville I and II hemoglobins* were seen in a survey in the Belgian Congo [91]. Stanleyville I resembles Hb L and P on electrophoresis at pH 8.6 but moves on chromatography at pH 6 like Hb D. Stanleyville II moves on electrophoresis like Hb D but moves on chromatography behind Hb D. Both hemoglobins were found in the extreme northeast of the Belgian Congo: the first in Nilotes and the second in a Bantu and in a partially Bantu partially Greek family living in a Nilotic area.

### Rare Fast Hemoglobins

*Hemoglobin I* was seen for the first time in an American Negro family where it was present in three generations [91]. It has always been seen in people of at least partial Negro descent. It is probable that a hemoglobin described as Hopkins I [61] is an example of this pigment. This hemoglobin has its mutational alteration in the  $\alpha$  chain in the same finger print peptide as Hb D, peptide No. 23. Hemoglobin I moves on electrophoresis at alkaline pH like Hb II but unlike Hb II moves at pH 6.3 toward the negative electrode.

*Hemoglobin J* was first seen in a young American Negro woman [94] whose father and six siblings also carried the abnormality. Further

parently suffering from thalassemia major was found to possess in addition to Hb A 74 per cent Hb F 12 per cent Hb A<sub>2</sub> and 5 per cent Hb Lepore. Since the mother possessed 11 per cent of Hb Lepore and the father had thalassemia minor with a Hb A<sub>2</sub> concentration of 5.5 per cent, it was concluded that the child suffered from a combination of the two abnormalities. Four other members of the family showed the Lepore hemoglobin in combination with Hb A and a slightly raised level of Hb F (2.3 to 2.6 per cent), they were considered to be heterozygotes.

The presence of some Hb F suggests that the Lepore trait is not simply a genetic replacement of part of Hb A. Gerald and Diamond [150] consider that the Lepore trait is more related to thalassemia than to the abnormal hemoglobin syndromes. It may be that Motulsky's interpretation of Hb H penetrance in association with thalassemia [68] is paralleled by the Hb Lepore trait, and that this pigment is seen in the phenotype only when a gene for thalassemia is also present. It has indeed been suggested that Hb  $\alpha_4$  which would correspond to  $\beta_4$  (H), might turn out to be the Lepore hemoglobin. The only efficient separation from Hb A has been achieved on starch slab electrophoresis at pH 8.6.

#### *The 'Rare Slow Hemoglobins'*

*Hemoglobin G* moves between A and S but separates from A when seen in the trait (Fig. 34-24). This hemoglobin was first seen in a West African family [121]; it may or may not be the same as the Hb G found in a family of Mediterranean extraction [10] which does not separate from Hb A on electrophoresis at pH 8.6. This latter hemoglobin has its mutational alteration in the  $\beta$  chain next to that where the S and C substitutions occur [67]. A hemoglobin with the electrophoretic and chromatographic properties of Hb G has also been seen in a Chinese woman [101]. Hemoglobin G is remarkable for not causing any abnormality in the homozygote.

*Hemoglobin L* moves on electrophoresis at pH 8.0 slightly behind G and in front of S. It was discovered in a family of North West Indian origin [152] and has since been found on seven different occasions always in Indians [103, 154]. Fingerprint studies have shown it to carry its mutational change in the  $\beta$  chain [150].

*Hemoglobin O* which moves on electrophoresis at pH 8.6 between E and S has been seen in 16 of 775 blood samples [26] from Buginese living on the Celebes (Bulawesi) [106]. Family studies have not been possible.

*Hemoglobin P* was first seen in American Negroes [57, 157] and has since been seen repeatedly in the Belgian Congo [63, 64]. It has the same electrophoretic properties at pH 8.0 as Hb I but can be differentiated from it by chromatography at pH 11 (cf. Fig. 34-13). Its mode of inheritance as well as other evidence, suggest that its mutational alteration is situated in the  $\alpha$  chain [63].

*Hemoglobin Q* was seen in a Chinese family [158]. The first patient also had Hb H. In this patient who suffered from a thalassemia like condition Hb Q replaced the A which is usually seen with Hb H. The only other person observed was the mother of the propositus who showed a hemoglobin mixture of 60 per cent Hb A and 40 per cent Hb Q. The mutational change in Hb Q is in the  $\alpha$  chain. Hb Q moves on electrophoresis at pH 8.6 just faster than Hb G and is again best differentiated from similar "slow" hemoglobins by chromatography at pH 6 (cf Fig 34-13).

Fig 34-24 Hemoglobin G on paper electrophoresis at pH 8.6. Hb G moves faster than S and D but separates clearly from Hb A.

*Stanleyville I and II hemoglobins* were seen in a survey in the Belgian Congo [91]. Stanleyville I resembles Hb L and P on electrophoresis at pH 8.6 but moves on chromatography at pH 6 like Hb D. Stanleyville II moves on electrophoresis like Hb D but moves on chromatography behind Hb D. Both hemoglobins were found in the extreme northeast of the Belgian Congo: the first in Nilotes and the second in a Bantu and in a partially Bantu partially Greek family living in a Nilotic area.

### Rare Fast Hemoglobins

*Hemoglobin I* was seen for the first time in an American Negro family where it was present in three generations [81]. It has always been seen in people of at least partial Negro descent. It is probable that a hemoglobin described as Hopkins I [61] is an example of this pigment. This hemoglobin has its mutational alteration in the  $\alpha$  chain in the same finger print peptide as Hb D: peptide No. 23. Hemoglobin I moves on electrophoresis at alkaline pH like Hb H but unlike Hb H moves at pH 6 toward the negative electrode.

*Hemoglobin J* was first seen in a young American Negro woman [84] whose father and six siblings also carried the abnormality. Further

examples have been seen in Indians, Indonesians and West African. Since identification is based solely on electrophoretic properties one might suspect that these widely distant places have given rise to different hemoglobins with the over all charge of hemoglobin J but with different peptide sequences. Hb J moves faster than Hb A and Hb K on electrophoresis at pH 8.6 and does not separate from A at pH 6.5 (Fig. 34.25).

Hemoglobin K moves on electrophoresis at pH 8.6 just in front of Hb A and barely separates from it. It was first seen in Algeria [79] and has also

Fig. 34.25. Comparison by paper electrophoresis at pH 8.6 of Hb A + H sample with one containing Hb J and S. Note that the distances S-J and A-H are the same. (The Hb J + S sample was kindly supplied from the first case of this condition seen by Drs J. E. MacIver and L. N. Went, University of the West Indies, Kingston, Jamaica.)

been seen in Liberia where it was described as Liberian II [88]. It has since been seen in other West Africans, in Southern Indians and in Bengalis. It is possible that Hopkins II is Hb K. This hemoglobin was inherited independently from hemoglobin S and its mutational change is in the  $\alpha$  chain.

Hemoglobin N was first seen in Liberia [86] and for a time "Liberian I" was thought to be Hb J. It moves only slightly faster than Hb J on paper electrophoresis at pH 8.6 but differs from Hb J by separating from Hb A at pH 6.5 and also on chromatography at pH 0 [73] (Fig. 34.26). Hb N has since been seen in a few instances in Portuguese territories in the northern parts of West Africa. It is possible that a hemoglobin provisionally described as "R" by Chernoff and found by him in association with Hb S is also Hb N. Hb N has also been seen in association with Hb S in West Africa. The mutational change is in the  $\alpha$  chain.

*Hemoglobin Norfolk* was observed after Hb Q and after the letter R was claimed provisionally for what might in fact have been an instance of Hb N. It was therefore decided to wait with giving the new hemoglobin a letter and it has been named after the county from which the family showing this fast moving hemoglobin was derived. This is an example of an abnormal hemoglobin in an English family with no known foreign connections. Hb Norfolk [89] resembles Hb J on electrophoresis at pH 8.6 and moves only slightly faster though it definitely moves more

Fig. 34.76. Hemoglobins J, K, and N on paper electrophoresis at pH 8.0. These hemoglobins move faster than Hb A in the order N, J, K.

slowly than Hb N. Hb Norfolk differs from Hb J by separating from A on electrophoresis at pH 6.5. This hemoglobin was discovered in a British airman in Singapore where it was the only abnormal European sample among 550 samples. It was then found in the father and in his brother in Norfolk, England. Its mutational change is in the  $\alpha$  chain. ✓

## WORLD DISTRIBUTION OF ABNORMAL HEMOGLOBINS

Anthropologists are particularly interested in human characters which are not so rare as to be of no general importance nor so widespread that they lose their value in distinguishing among different human populations. For anthropologic purposes perhaps the ideal characters among the abnormal hemoglobins are Hb C and E. Both pigments are present in millions of human beings but at the same time they are peculiarly associated only with certain well-circumscribed groups of people [159]. Hb C discovered in American Negroes could be expected to have come with their ancestors from West Africa but it was surprising to find that Hb C which is not frequent in American Negroes should turn up in 10 per cent of the inhabitants of Accra in Ghana. On the other hand no Hb C is seen in East Africa nor is it found in the Belgian Congo. Occasionally examples have been seen in South Africa or in Central Africa.

but there is always a readily traced connection with West Africa. Within that part of the continent again fairly sharp geographic demarcations are noted. Westwards from Ghana the incidence falls until it becomes very low in Liberia, and there is a similar decline eastwards, where in the Yoruba in western Nigeria the incidence is only about half that found in the coastal region of Ghana. This was even more impressive when it was seen that within Nigeria the River Niger forms a barrier to the spread of

Fig. 34-27 World distribution of major hemoglobin abnormalities

the hemoglobin westwards in the Yoruba. Hb C is found in 5 to 6 per cent of the population east of the river in the Ibo; the incidence amounts to only a fraction of 1 per cent. In Ghana itself the frequency of the Hb C gene increases towards the north; in the northernmost territories of Ghana and in the neighboring French High Volta territory one fifth of the population possess Hb C in their red cells. There is therefore a center of high frequency somewhere in the north of Ghana, with a fall in frequency to the south, east and west. Neel once stated that never in the history of genetics, with the possible exception of Ford's melanism story in the moth, have geneticists and those with kindred interests been quite so close to having a ringside seat at the origin and dissemination of a new gene. (Fig. 34-27)

Hemoglobin E presents a similar situation. Again a very high frequency is found in Burmese and their immediate neighbors but not in Indians in nearby Bengal, Tibetans or Indonesians. There are small foci with a high incidence in the Indonesian archipelago but such a local increase would be expected for any gene in small islands with an inbreeding population. Of particular interest is that Hb F is found in the Indo-Chinese but not in the Chinese and that it is therefore linked with the earlier Mongoloid populations of Southeast Asia. In Malaya there is a higher

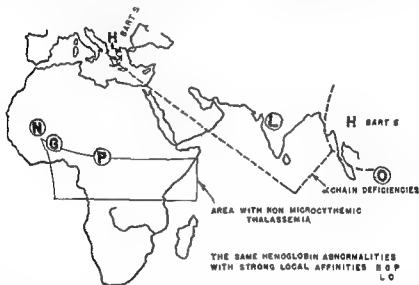

Fig. 34.99. The rare hemoglobin abnormalities with strong local affinities: Hb N, G, L, and O.

incidence in the north. Less hemoglobin E appears in the south where immigration from Indonesia has been of greater importance. Of the primitive populations the Vedda of Ceylon have a high Hb F frequency which links them with the proto-Malays rather than with the Veddoids of southern India in whom sickling but no Hb E is found. This throws an entirely new light on the racial affinities of these Veddoids which is actually borne out by their physical appearance. Of the few proto-Malayan Pygmies examined several were Hb E trait carriers but no Hb E was discovered in the Negritos of the nearby Andaman Islands.

Hemoglobin S is more widely spread. It is found in tropical Africa in the west as well as in the east. In the east there are striking differences between the Hamitic tribes with few if any sickle cells and the Bantus and Nilotes with high sickling rates. There is evidence for a westward spread of the sickling gene and in Liberia sickling is less frequent in the

older and longer-established populations Hb S is also found in India but predominantly in primitive tribes which are the least likely to have been in contact with Africa. It has been proposed that the African continent and India inherited the sickling gene independently but from a common source in the Middle East. This would well agree with what is known of population movements from the Middle East towards the southeast into India.

Hemoglobin D is found at high frequency in India, but it now appears that Hb D<sub>s</sub> is more associated with Europeans in whom it is found occasionally, and that the Hb D itself is not uniform in India either and may be D<sub>s</sub> or D<sub>r</sub>. In India Hb D and Hb L are found in similar populations the first at high and the second at rarer frequency. Although rare whenever Hb D has been discovered in Africa it has been in areas associated with the most westerly regions where it is known to occur. It might be a mutation peculiar to the older inhabitants of that continent.

It is remarkable that the  $\alpha$  chain deficiencies Hb H and Hb Bart's should be seen in Mongoloids such as Chinese and Thais on the one hand and in Greeks on the other (Fig. 34.28).

### POPULATION DYNAMICS OF THE ABNORMAL HEMOGLOBINS

It is tragic that in Africa virtually no homozygotes for the sickling gene reach adult life. Many surveys particularly in East, West and Central Africa have either failed to find sickle-cell homozygotes in the adult population or have discovered them only exceptionally. It is therefore surprising that the gene is present at a high frequency in many parts of that continent [160]. The steady drain caused by the early death of homozygotes would be expected to cause a fall in the incidence of Hb S. Frequencies of 40 per cent and more of the sickle-cell trait can be understood only if there exists a special compensating mechanism which replenishes the Hb S pool in every generation. Neel [161] in 1953 discussed the implications of a situation in which the sickling gene was constantly eliminated by early death of homozygotes but in which a high frequency was nevertheless maintained. One possibility is that a high mutation rate for the sickling gene is a peculiar characteristic of these populations and replaces the genes lost in every generation by sickle-cell anemia. Such an explanation would require a mutation rate about three thousand times greater than those hitherto calculated for man [162] and in a search for evidence to put this theory to the test in tropical Africa no support could be found for it in an extensive survey [163]. The other possibility suggested by Neel is that a balanced polymorphism exists by which the Aa heterozygote enjoys two or more advantages not shared by either homozygote. Allison [162] found evidence that sickle cell

trait carriers enjoy an immunity against malaria which is not shared by the normal homozygote

Several investigators have shared in developing the concept of balanced polymorphism as the genetic mechanism supporting the persistence of the sickling gene at high frequency. Early observations were made in Rhodesia [164-165]. It is of the greatest importance that two points be kept in mind. It is necessary to single out for investigation the effect of *Plasmodium falciparum* and to separate it from the part played by other parasites because only *P. falciparum* causes malignant malaria which kills children in infancy. In these children it is necessary to consider only the age at which immunity against the parasite had not yet been acquired. Immunity is acquired very early in hyperendemic areas and studies of adults or even of children above the age of 2 include many individuals with partial protection against *P. falciparum* some of whom would be sickle-cell trait carriers and normal homozygotes [166]. The protection against malaria afforded to sickling infants could by itself fully explain the high sickling rate in some African populations. The mechanism of protection might be a failure of *P. falciparum* to thrive on sickle-cell hemoglobin or it might be related to the fact that cells infected with this parasite tend to adhere to the vessel wall where they would become deoxygenated. This would cause them to alter their shape and the sickled cells would then be phagocytosed [167]. The latter is the more probable explanation because cells containing Hb S do not differ from normal cells when they are used for culture of *P. falciparum* in vitro [168]. Survival of homozygotes plays little part in maintaining the sickling gene at least in some parts of Africa [169-170]. The protection in infancy of the heterozygotes against malignant malaria is not only the first but also the most striking example for balanced polymorphism acting in the natural selection of the human race.

There is a remarkable correlation between high sickling rate and low social status [171]. The lower the social level of a human group usually the greater is its isolation and inbreeding populations are notoriously likely to accumulate specific characters at a higher frequency than societies with a larger gene pool. There is yet another factor which would tend to raise the sickling frequency in the more primitive tribes in the less accessible parts of Africa. Although the malarial pressure may not be greater the malarial death rate will be increased with unfavorable living conditions [172]. This would explain why the sickling rate is higher in some areas of Africa where the intensity of malarial infection is less than in others with a greater incidence of the sickle-cell trait. With an over all increase in the death rate any differences due to protection against malaria will become more significant. This suggests that the improvement of living conditions as well as the eradication of malaria will cause a fall in the sickling incidence in future generations.

It has not been possible to find a difference in malarial infection between normal homozygotes and carriers of the Hb C trait [173]. It has been suggested that Hb I might be responsible in part for the 'inborn' protection of infants against malaria, as for Hb E and D it has been pointed out that homozygotes who would on the whole be viable and are known to produce children would be protected against thalassemia [174]. Thalassemia acts by interference with the production of Hb A and should therefore have no effect on homozygotes for Hb E or D. In heterozygotes the only conditions which could arise would be Hb I thalassemia and Hb D thalassemia respectively. These hemoglobinopathies are much less severe than thalassemia major. It is noteworthy that both Hb E and D are found in parts of the world where it is now known that the incidence of thalassemia is high and where thalassemia major is the only hemoglobin disease which will cause the death of the affected persons with near certainty before they are able to produce children. Other advantages of Hb E and D might be related to the red cell morphology of the homozygous conditions. The blood picture resembles that of patients with a compensated iron deficiency. There is a polycythemia without a rise in total red cell volume and perhaps such individuals can adapt themselves more easily to an iron deficient diet or to secondary iron deficiency in hookworm disease [143-170].

## THALASSEMIA

Thalassemia is an erythroblastic anemia beginning early in life which in its severe form is associated with enlargement of spleen and liver, a leukemoid blood picture and characteristic bone changes. Throughout the last 70 years the concept of this disease has undergone continuous change. It is now known that the condition described by von Jaksch in 1889 which he called *anemia pseudoleukaemica infantum* and which was latter named *Jaksch Hayem Luzet anemia* included besides thalassemia such different conditions as iron deficiency anemia complicated by bacterial infection and the anemia associated with splenomegaly and cirrhosis (Banti's syndrome).

In 1925 Cooley and Lee [176] described the severe form now known as thalassemia major. The name *thalassemia* or Mediterranean anemia (*θαλασσα* = Mediterranean Sea) was chosen [177] because it seemed at first that the disorder was found exclusively in families of Mediterranean stock. Contribution from Italy and Greece [178-183] prepared the ground for the recognition that there are two similar familial conditions which vary in severity and that the major disability is found in the homozygous state. The milder condition was also described in the United States where it was named *target cell anemia* and *familial microcytic anemia* [184-186].

Here also severity seemed less when the gene responsible for the abnormality was inherited as a single dominant trait [184, 185]

The key investigation which conclusively proved the mode of inheritance was that by Valentine and Neel [187, 188] this study was complemented by that of Silvestroni, Bianco and Villisneri in Italy [189, 190]

### CLINICAL AND GENETIC DEFINITIONS

There are two ways of using the terms *thalassemia major* and *minor*. They are often employed to describe the severe and mild forms of the disease respectively. The term *thalassemia intermedia* has been introduced to describe disease states which are midway in clinical severity between *thalassemia major* and *minor* and *thalassemia minima* has been used when the signs and symptoms are less than in *thalassemia minor*.

When it was thought that all homozygotes suffer from severe *thalassemia* and all heterozygotes from mild *thalassemia* the clinical and genetic interpretations of these terms were taken to be interchangeable (Fig 34-29). Although this is permissible for most cases of *thalassemia* there are a significant number of heterozygotes who suffer from a hemoglobinopathy which can hardly be considered a minor type. Some of these have later been found to combine the heterozygous state for *thalassemia* with that for an abnormal hemoglobin but others have also been proved to be solely heterozygous for *thalassemia*. The explanation is that the *thalassemia* gene is in a sense always dominant and almost always causes some symptoms although the penetrance of the gene may vary. Also since symptoms are present already, however mild they may be they may be exacerbated when additional stress is experienced. A heterozygote for the hemoglobin C gene for example suffers from no known disadvantage. In the presence of bronchopneumonia or of pregnancy the new burden imposed on the hematopoietic system will affect the patient no differently than it would a normal individual. In a *thalassemia* heterozygote however slight symptoms would become exaggerated because the auxiliary mechanisms of blood production have already been called into action and may now no longer be capable of the expansion required for the maintenance of a normal hemoglobin level. Numerous instances of *thalassemia* in heterozygotes have in fact come to notice because of chronic hemorrhage or pregnancy. It would seem more helpful to reserve the terms *major* and *minor* for the genetic types and to describe the clinical conditions as severe, mild or symptomatic. This convention will be employed here.

### PATHOGENESIS

In *thalassemia* the principal disability is failure to produce red cells with normal hemoglobin content. The hemoglobin concentration may not

Fig. 31-29. Family trees of patients suffering from thalassemia major (By permission of M. H. Strauss et al. [186].)

be much below normal in these cells but they are reduced in volume. The association of a low mean corpuscular volume with a normal or near normal mean corpuscular hemoglobin concentration is sometimes useful in differentiating the hypochromic anemia of thalassemia from that of iron deficiency. There is a deficiency in Hb A production [191] because of

a disturbance in formation of ferroporphyrin [192 193] or possibly in some instances because of an abnormality in the earlier stages of porphyrin synthesis [104 105]

There is also in thalassemia increased hemolysis in the peripheral blood [196 197] By using  $\text{Fe}^{59}$  to determine the sites of red cell production and to measure bone marrow activity and  $\text{Cr}^{51}$  to measure red cell survival it has been demonstrated that red cell production per unit bone marrow

Fig 34 30 Appearance of the bones in thalassemia major The hypertrophy of the bone marrow causes replacement of the cortex The thinning of the cortex is compensated by numerous small trabeculae giving a mosaic pattern The metacarpals are quadrangular (By permission of Drs A W Franklin and A R Kamp Ho per St Ba tholomew a Hospital London)

is decreased but that total red cell production is greater than normal [198] Destruction of red cells is accelerated and depending upon the equilibrium which the patient establishes between increased production and increased destruction the anemia may be more or less severe At whatever level the equilibrium is finally placed it is obvious that additional blood destruction as in infectious diseases or additional demands as in pregnancy will tend to disturb the delicately balanced state

The clinical manifestations of thalassemia can all be related to the decrease in bone marrow activity per unit active tissue and to the increase in peripheral hemolysis In childhood the first observation in thalassemia is that the patient is pale and listless Intercurrent infections are poorly

resisted Splenomegaly and with lesser regularity, hepatomegaly are noted early. The extension of bone marrow activity into areas of the skeleton which usually do not contain blood forming tissue and the hypertrophy of the bone marrow in those bones where hematopoiesis normally occurs affect the appearance of the skeleton. There is thinning of the cortex of the long bones and the structure is supported by numerous trabeculae (Fig 34-30). X ray study discloses the mosaic pattern of this trabeculation. The diploe of the skull thickens because of marrow hypertrophy, and the outer and inner tables are thin. Perpendicular trabeculation causes the x ray to have a 'hair-on-end' appearance. The thickening of the cranial bones together with a relatively sunken nose, result in a 'mongoloid' facies.

#### APPEARANCE OF THE RED CELLS

None of the features of thalassemia is absolutely constant. Of the various abnormalities changes in the red cells are found with most

Fig 34-31 Red cells in thalassemia major. Note the thinness of the cells, their unequal size, oval and irregularly shaped cells, and target cells.

regularity. The overactivity of the bone marrow is reflected in the appearance of nucleated erythrocytes in the peripheral blood and in an increase in reticulocytes. The red cells are thin and vary in size. Abnormally shaped cells appear. Since the cells are flatter than normal they tend to appear as 'target cells' in the blood smear and can be recognized *in vitro* by their increased resistance to lysis by hypotonic salt solutions. If the morphologic features of the red cells are used as the criterion for

diagnosis the reduced osmotic fragility is the most useful feature [199] The stimulation of the bone marrow often also results in an increase in white cells to give the leukemoid reaction first noted by von Jaksch (Fig. 34 31)

### HEMOGLOBIN IN THALASSEMIA

Hemoglobin F is nearly always found in thalassemia major and frequently in thalassemia minor It has been doubted whether the alkali-resistant hemoglobin in thalassemia is in fact the same pigment as that found in the newborn but the majority of investigators are now agreed that there are no chemical differences between the two alkali-resistant hemoglobins Further rabbit serum prepared to agglutinate specifically the red cells of the newborn agglutinates also cells of patients with thalassemia [200] Hb A<sub>2</sub> is increased in thalassemia from the usual 2 to 3 per cent to 3 to 5 per cent It can be assumed that both Hb A<sub>1</sub> and Hb F are produced in greater quantity because the quantity of Hb A<sub>1</sub> is reduced A relation has been found between the concentration of Hb A<sub>2</sub> and individual thalassemic families [201] The amount of Hb F however varies widely and members of the same family may show widely different concentrations of this pigment Neither the level of Hb A<sub>2</sub> nor that of Hb F can be correlated in individual patients with the severity of their condition In double heterozygotes for the thalassemia gene and for a gene determining a variant of normal adult hemoglobin such as Hb S or Hb C, only the formation of Hb A seems affected Whereas in a sickle cell trait (AS) more Hb A is present than Hb S the proportion is reversed in sickle cell thalassemia

### HETEROGENEITY OF THALASSEMIA

None of the characteristics of thalassemia can be expected regularly in all cases Gouttas [202] found among 217 heterozygotes that only 99 showed the morphologic features of thalassemia as well as an increase in the Hb A<sub>2</sub> component and a persistence of fetal hemoglobin Of the remainder 109 had the typical red cell picture and an increase in Hb A<sub>2</sub> but with no Hb F Two possessed both abnormalities in hemoglobin composition but had normal red cells and two had abnormal red cells and Hb F but failed to show an increase in Hb A<sub>2</sub> Two showed an increase in Hb A<sub>2</sub> as the only feature and three abnormal red cells without any hemoglobin abnormality A study of parents of patients with thalassemia major showed that the thalassemia gene may be transmitted without any signs of thalassemia [203]

There is now ample evidence that the red cell morphologic changes of thalassemia and the suppression of Hb A production can occur independently The dissociation was first observed in sickle cell heterozygotes Whereas sickle-cell thalassemia usually combines features of sickle cell

anemia with the red cell morphologic appearance of thalassemia, a number of families have now been studied in which the combination of Hb S with Hb I and little or even no Hb A was not associated with leptocytosis.

Parents without sickle cells and children of these individuals may show an increased proportion of Hb I without microcytosis and in some cases without an increase in Hb A<sub>2</sub> [204-208]. Microcytosis without Hb I has been described as a new type of hemoglobinopathy [210] or as 'anemia hypochromica sideroblastica hereditaria' [209]. The finding of Hb I without microcytosis has been termed variously 'nonmicrocythemic thalassemia', 'hereditary persistence of fetal hemoglobin' or the 'I gene' condition. Gerald [148] has gone so far as to postulate a "new" hemoglobinopathy for any thalassemic condition found without an increase in Hb A<sub>2</sub>.

There is no doubt that the dissociation of the features of thalassemia is most easily explained on the basis of a multiplicity of genes which are usually inherited together but which can also be transmitted independently. The inheritance of one 'nonmicrocythemic' and one 'classical' thalassemia gene results in typical thalassemia major [211] as does that of the I<sup>epore</sup> trait together with a single gene for classical thalassemia [201]. Hemoglobin H disease is now recognized as being allied to thalassemia and as requiring the inheritance of at least one thalassemia gene. Yet in this condition Hb A<sub>2</sub> is reduced rather than increased. On the other hand, no noticeable deficiency in Hb A<sub>2</sub> has been noted in thalassemic children with Hb Bart's. This is surprising because both Hb H and Hb Bart's are  $\alpha$  chain deficiencies, one presenting as an excess of the  $\beta$  chain of adult hemoglobin, and the other as a tetramer of the fetal  $\gamma$  chain. In two patients with  $\beta$  chain deficiency in both fetal and adult hemoglobin resulting in both Hb H and Bart's, Hb A<sub>2</sub> was reduced as in Hb H disease.

The multiplicity of the thalassemia genes is borne out further by family studies which have demonstrated that in some families the thalassemia gene is inherited independently of the sickling gene and in others in a manner which suggests either alikism or close linkage [212, 213]. There can be little doubt but that the early suggestions that there might exist several thalassemia genes [8, 214-215] heralded a picture of much complexity. The diagnosis of thalassemia is today a collective concept no less than was the von Jaksch-Hayem-Luzet syndrome two or three generations ago.

#### GEOGRAPHIC DISTRIBUTION OF THALASSEMIA

Most of the early work on thalassemia was on families of Mediterranean origin. There is now no doubt that the term is a misnomer and that thalassemia is most commonly found in Asia. Cases observed in Turks, Persians, Kurdistan Jews [216-218] and even those seen in India [220]

might be related to cases among the Mediterranean populations but this explanation fails to account for thalassemia in Thailand [221]. Although no survey has yet been made in China, Chernoff [222] lists eight accounts of thalassemia in Chinese, most all of whom originated from the area around Canton and Hongkong. One of the authors of this chapter (H. L.) has seen thalassemia in eight Chinese families in London, England. Numerous observations have been made in Indonesia [223] and the Philippines [224].

### POPULATION DYNAMICS OF THALASSEMIA

The homozygote for thalassemia suffers from a severe disease and only rarely survives into adult life. Those who do are sexually immature. Yet in Italy alone the number of thalassemic individuals has been estimated to surpass 1 000 000. A world incidence of many tens of millions would not be an exaggerated estimate.

The high frequency of a gene which for all practical purposes cannot be transmitted by the homozygote and which may cause disease even in the heterozygote requires an explanation. It has been suggested that parents of children who died of thalassemia major might tend to overcompensate their loss. Since both parents would be heterozygous for thalassemia, a greater fecundity from such unions would result in an increase in the number of heterozygotes in the following generation. The theory of overcompensation has been carefully tested in Italy but the available evidence failed to support it [225].

Haldane [175] has made an alternative suggestion that a balanced polymorphism might favor the survival of the thalassemia heterozygote. He suggested that while the abnormal homozygote dies from the anemia, the normal homozygote might be less capable than the heterozygote of adjusting his blood formation to an iron or vitamin deficiency. How such a protection against iron deficiency in the heterozygote might come about has been described by Sjpestejn [226]. Women with thalassemia minor tend to have a mild hypochromic anemia which causes them to increase iron absorption. Since in thalassemia iron utilization for hemoglobin production is decreased, these women would store their iron and eventually would have larger deposits of this element than normal women. They would then be better protected against the iron deficiency anemia of multiparous women which so often is the cause of death in this group in primitive populations. They would also presumably have an advantage when ancylostomiasis causes chronic hemorrhage and subsequent iron deficiency. Haldane also suggested that thalassemia heterozygotes might be better protected against malaria than normal homozygotes and some evidence for this theory has been found in Sardinia [227]. Of two racially identical populations one lived in a highly malarious region and also showed a high frequency of the thalassemia gene and

the other lived in a healthier area and showed a much lower incidence of this abnormality

Whatever the genetic advantage of the thalassemia gene has been in the past or is today in underdeveloped countries the inheritance of thalassemia is now a major problem in some advanced countries where infantile mortality due to other causes such as infection and malnutrition has fallen. Marriage advice has been widely advocated in Italy. The results of the work on bone marrow transfusion and transplantation undertaken in conjunction with leukemia and radiation damage will have to be followed with the greatest attention by those interested in the thalassemia problem and indeed that of the hemoglobinopathies as a whole. One might plan such transplantations for the newborn when antibody formation is still undeveloped. Perhaps the day will come when every child of two parents with the thalassemia trait (or the sickle-cell trait) will receive a bone marrow transplantation from either or both parents at birth without any delay for the diagnosis of the infant's own hemoglobin genotype.

## SUMMARY

1 The hemoglobins of man are a group of pigments each of which is composed of four molecules of ferroporphyrin IX attached to one molecule of globin. The hemoglobins differ in the properties of the globin moiety.

2 At birth fetal hemoglobin Hb F predominates. In normal man this is rapidly replaced by the normal adult pigment Hb A. Hb A consists of at least two components: a major one, A<sub>1</sub>, and a minor component Hb A<sub>2</sub>.

3 The globin molecule consists of two identical half molecules each of which contains two different long peptide chains. In Hb A these are the  $\alpha$  and  $\beta$  chains, and in Hb F the  $\alpha$  and the  $\gamma$  chains. The variant hemoglobins contain either altered combinations of the four chains or altered amino acid sequence within the chains. Each type of chain is thought to correspond to one gene and the inheritance of the polypeptide chains is codominant.

4 Abnormal hemoglobins are principally identified by their electrophoretic properties. The most important abnormal hemoglobin is sickle-cell hemoglobin Hb S, which is responsible for the sickling phenomenon in sickle cell disease. Reduced solubility of Hb S under reduced oxygen tension is responsible for the various clinical and laboratory phenomena of the disease. Heterozygotes for Hb S and Hb A are not anemic, but heterozygotes for Hb S and for other abnormal hemoglobins or for thalassemia may be anemic if Hb S becomes the predominant hemoglobin.

5 Almost all hemoglobins contain  $\alpha$  chains. The exceptions are Hb H, which has four  $\beta$  chains, and Hb Bart's, which has four  $\gamma$  chains. Of the

$\alpha$  chain hemoglobins only one Hb F which is  $\alpha_2\gamma_2$  contains no  $\beta$  chains. The other  $\alpha$  chain hemoglobins are normal hemoglobin tho with an  $\alpha$  chain mutational change (Hb D, I, P and Q) and those with a  $\beta$  chain mutational change (Hb S, C, D, E, F, G, J, L and N). The properties and clinical significance of these and other less well characterized hemoglobins are described in the text.

6 The world distribution of the variant hemoglobins has provided important anthropologic data and has contributed to the study of population dynamics. In the case of Hb S the high frequency of trait carriers is thought to derive from a selective advantage of Hb AS heterozygotes in areas with high mortality from *P. falciparum*.

7 Thalassemia or familial microcytic anemia is not known at present to be the result of an abnormality of hemoglobin structure but rather may be an abnormality in the rate of synthesis of Hb A. The inheritance pattern in the majority of families studied is codominant with and segregating independently of abnormal hemoglobin traits. Thalassemia and abnormal hemoglobins may coexist and their combination is often manifested by anemia.

## Chapter 35

### The Blood clotting Factors

---

*Rosemary Biggs and Lamont W. Gaston*

This chapter is concerned with the clotting of the blood with the specific factors which normally participate in that complicated process and with those diseases which appear to have a genetic basis and which arise because of specific deficiencies in the clotting factors. It must be said at once that the clotting factors are not known as specific chemical species (excepting  $\text{Ca}^{++}$ ) and the reactions which they undergo or catalyze are known only phenomenologically. Accordingly the diseases of the clotting of the blood cannot be given the precise biochemical definition that is the goal of science; that level of understanding must await the painstaking work of the coming years. The reviewers are perforce satisfied to provide a summary of the current status of a problem which is decidedly unfinished business.

Flow of blood from a minor injury usually stops spontaneously and the shed blood clots at about the same time as the blood flow ceases. Moreover, if the blood flow fails to stop in many instances a solid clot also fails to form. These commonplace observations suggest that the clot stops the flow. Indeed the whole superstructure of blood coagulation theory is based upon the assumption that there is a causal relationship between hemostasis and coagulation. It may come as a surprise that this fundamental tenet has been verified only experimentally through the study of hemorrhagic states. This indirect approach to normal coagulation and hemostasis through study of the hemorrhagic diseases is made necessary by unusual experimental limitations. The extent of the limitations must be understood if the problem of hemostasis is to be viewed in reasonable perspective.

Normal blood in a glass tube will clot. Formation of the clot may be observed at different temperatures in recalcified plasma in containers with different surfaces and in plasma with and without platelets. If the sample of blood has defective coagulation the scope for study is immedi-

## THEORY OF BLOOD COAGULATION

## CLASSICAL THEORY

The modern era of blood coagulation research began with the classical theory at the end of the last century. According to the postulated scheme blood clotting follows two simple reactions:

The basis for this formulation was sound and much subsequent work supported it. It is not proposed to discuss its foundation but to take it as an established starting point for modern developments. The history of the theory of blood coagulation has recently been reviewed elsewhere [1].

According to this theory prothrombin is the one precursor of the coagulant thrombin. The reaction is accelerated by a tissue extract called thromboplastin and requires the presence of Ca<sup>++</sup>. The thromboplastin used experimentally is usually a saline extract of fresh or dried brain or lung tissue or on occasion the venom of the Russell's viper (RVV). The venom is a powerful coagulant which differs in its activity

ately increased. Abnormal and normal samples may be mixed. The normal sample may be fractionated to see which component will correct the abnormality in the abnormal sample. When the fraction has been isolated and identified a reconstructed normal system can be devised in which the effects of omitting and including the pertinent fraction can be studied. It is then usually possible to suggest a theory of normal coagulation to include the plasma fractions under study. Invention at this stage may suggest a method for studying and even measuring the abnormality in other similar patients. In this way most of the normal coagulation factors have been discovered and most useful techniques devised.

As more and more different types of defect are studied the number of possible mixture experiments increases and the theory becomes more complex to accommodate all the newly postulated factors in a new normal scheme. This evolution proceeds through phases of comparative clarity when most observed facts fit some hypothetical scheme and phases of revolutionary change when the hypotheses receive complete revision and the whole significance and interpretation of techniques must be reappraised. Thus a test which was used with confidence as a measure of prothrombin at one phase may be interpreted as a quantitative measure of factor V or VII at a later time.

The uncertainty of the whole approach has naturally not commended the subject to the biochemist and it must be admitted that the whole superstructure of theory and hypothetically interpreted methods has become very large. In fact the inclusion of this subject in a book which deals mainly with the biochemical basis of inherited diseases may be unwarranted. However the subject appears to be in an interesting phase which may be approaching transition, a phase when a review emphasizing difficulties and inconsistencies may help to turn the kaleidoscope to a new and more intriguing pattern.

It is proposed to begin the survey with a brief and undocumented account of the history of the theory of blood coagulation and to use it as a skeleton for reference during a more detailed consideration of the coagulation factors and hemorrhagic states. Details of technique will be introduced as the need arises. Finally an attempt will be made to relate the information reviewed to the role of coagulation in hemostasis. A listing of coagulation factors and synonyms appears in Table 35 I.

The subject matter will be limited to those inherited defects which are reasonably clearly defined. For this reason reference to inhibitors of blood coagulation has been omitted; patients with inherited abnormality of the inhibitors of coagulation are too rarely encountered to merit discussion. The platelet defects classed as thrombopathy are omitted because the literature on this subject is still confusing and the different entities are not clearly defined.

TABLE 35-1 COAGULATION FACTORS AND SYNONYMS

| <i>Not common name</i>                    | <i>Synonyms</i>  | <i>Numerical term</i> |

## THEORY OF BLOOD COAGULATION

## CLASSICAL THEORY

The modern era of blood coagulation research began with the classical theory at the end of the last century. According to this postulated scheme blood clotting follows two simple reactions:

The basis for this formulation was sound and much subsequent work supported it. It is not proposed to discuss its foundation but to take it as an established starting point for modern developments. The history of the theory of blood coagulation has recently been reviewed elsewhere [1].

According to this theory prothrombin is the one precursor of the coagulant thrombin. The reaction is accelerated by a tissue extract called thromboplastin and requires the presence of Ca<sup>++</sup>. The thromboplastin used experimentally is usually a saline extract of fresh or dried brain or lung tissue or on occasion the venom of the Russell's viper (RVV). The venom is a powerful coagulant which differs in its activity

from mammalian tissue extracts (see below) Thrombin converts fibrinogen to fibrin which forms the matrix of the clot

#### FIRST MODIFICATION FACTORS V AND VII AND THE STUART PROWER FACTOR

This convenient way of accounting for clotting was jolted by observations made over a period of several years that certain patients with faulty clot formation were defective in one of three specific factors necessary to the rapid conversion of prothrombin to thrombin The *c* factors are now known as factors V and VII and the Stuart Prower factor In these cases examination of the blood showed a slow conversion of prothrombin to thrombin in the presence of tissue thromboplastic extracts and  $\text{Ca}^{++}$  Biggs, Douglas and Macfarlane [2] and Hardisty [3] have shown that factors V and VII in the presence of  $\text{Ca}^{++}$  react with mammalian tissue extract thromboplastin to form an active substance which converts prothrombin to thrombin Owren, Rapaport Hjort and Aas [4] found that the product of this reaction can be sedimented by centrifuging as an *active particulate material*

Stuart Prower factor resembles factor VII in its physicochemical characteristics its deficiency on a hereditary basis gives rise to a hemorrhagic state indistinguishable clinically from factor VII deficiency The mechanism by which these three factors allow tissue thromboplastic extracts to effect the rapid conversion of prothrombin to thrombin is unclear Thus the classical theory had to be rewritten with the product of interaction of tissue extract  $\text{Ca}^{++}$  factors V, VII and Stuart Prower factor being termed *prothrombinase*

The term prothrombinase has been used by Owren [4] for the direct activator of prothrombin Russell's viper venom is not entirely interchangeable with tissue extract in forming prothrombinase The plasma from patients with factor VII deficiency (see below) reacts normally if PVV, lipid<sup>1</sup> and  $\text{Ca}^{++}$  are used brain extract fails to activate the clotting system fully It seems probable that RVV requires lipid and both factor V and the Stuart Prower factor for optimum activity Experiments with

<sup>1</sup> Lipid is any one of several fatty substances such as cephalin

RVV probably have no physiologic significance but it can be employed for diagnostic purposes with various pathologic samples (Table 35 2)

TABLE 35-2 PROPERTIES OF FACTORS I AND VII AND THE STUART PROWER FACTOR

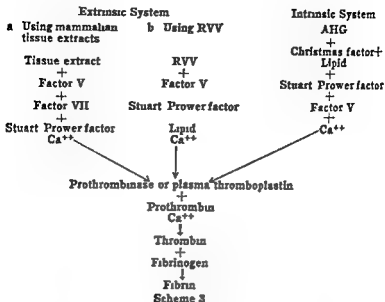

| Properties                    | Factor I     | Factor VII          | Stuart Prower factor |
|-------------------------------|--------------|---------------------|----------------------|
| Stability on storage          | Unstable     | Stable              | Stable               |
| Presence in normal serum      | Absent       | Present             | Present              |
| Adsorption by inorganic salts | Not adsorbed | Adsorbed            | Adsorbed             |
| Required for normal action of |              |                     |                      |
| 1 Brain extract               | Required     | Required            | Required             |
| RVV                           | Required     | <u>Not required</u> | Required             |
| 3 Plasma thromboplastin       | Required     | <u>Not required</u> | Required             |

#### SECOND MODIFICATION HEMOPHILIA AND CHRISTMAS DISEASE FACTORS AND BLOOD THROMBOPLASTIN FORMATION

An unsatisfactory feature of the classical theory even in its modified form was that it paid no attention to hemophilia the most important single coagulation defect. In hemophilic blood all the factors envisaged by the classical theory are present in normal amounts. In order to study the hemophilic defect it was necessary to ignore the theory and to study the subject from first principles.

An early observation was that a fraction of normal plasma containing fibrinogen (Cohn fraction I) would correct the hemophilic abnormality *in vitro*. The correcting substance came to be called antihemophilic globulin (AHG). It would not work properly without platelets. Later it was found that a very powerful activator of prothrombin resembling prothrombinase could be formed from reagents derived entirely from normal blood. This substance is called plasma thromboplastin. At first it was thought that the substances necessary for plasma thromboplastin formation were AHG, platelets, factor VII, factor V and  $\text{Ca}^{++}$  but later work showed that this view was incorrect. Factor VII is not required for plasma thromboplastin formation but two factors the Christmas factor (plasma thromboplastin component or ITC or factor IX) and the Stuart Prower factor are required.

It is evident that the tissue and plasma prothrombin converting systems are similar and use certain components in common but they are different in their origin and in some of their requirements. For convenience the system involving tissue extracts or RVV is called the extrinsic thromboplastin system and that derived wholly from blood constituents is called the intrinsic thromboplastin system. The scheme can now be visualized as follows:

**THIRD MODIFICATION \ SURFACE CONTACT,  
PLASMA THROMBOPLASTIN ANTECEDENT (PTA)  
AND THE HAGEMAN FACTOR**

If whole normal blood is collected into glass and silicone treated tubes the blood in the silicone tube takes longer to clot than that in the glass

tube. Some reaction occurs on exposure of blood to glass. Evidence now suggests that two factors—the Hageman factor and the I PA factor—are concerned in the changes brought about by glass. Probably the Hageman factor is activated by contact. The activated substance then reacts with the PTA factor to produce another active product. This product is probably concerned in the activation of the Christmas factor.

To conclude this summary a sequence of possible reactions is given above. It should be realized that this scheme is highly hypothetical. The five active intermediate products proposed may have no basis in reality, and indeed the whole process may be found to involve a series of parallel reactions rather than a sequential chain of reactions.

## CLINICAL COAGULATION DEFECTS

### *Afibrinogenemia*

A brief glance at any of the coagulation schemes will show that there can be no clot when there is complete absence of fibrinogen from the blood. This particular defect is extremely rare.

The diagnosis of afibrinogenemia is easily made clinically. Plasma from such a patient does not clot upon the addition of thrombin, nor is there a visible precipitate with 25 per cent  $(\text{NH}_4)_2\text{SO}_4$  fractionation.

Typical cases have been described by Macfarlane [5] and Fernando and Dharmasena [6]. Neither of these patients was a severe bleeder. Both bled at the separation of the umbilical cord and from superficial abrasions. Neither had any hemarthroses or deep muscle hematomas. One (the patient of Fernando and Dharmasena) was admitted to hospital and operated on successfully for hemoperitoneum. The other died at the age of 28 from retroperitoneal bleeding.

Of great interest has been the mildness of the hemorrhagic diathesis in some of the reported cases. Some of the females have had normal menses, and the unusual complication of hemarthrosis does not seem to result in permanent crippling of the joint.

The generation of thromboplastin and thrombin has been found to be normal; it seems that only the synthesis of fibrinogen is defective. Gatlin and Borges [7] have shown that the half-life of fibrinogen infused into two such patients is approximately 4 days, a survival comparable to that in normal individuals.

**Genetics.** The two patients mentioned and many of the others recorded were the offspring of consanguineous marriages. Both sexes are affected, the defect being transmitted as an autosomal recessive trait. Patients exhibiting the clinical picture are considered to be homozygous for the defect. Multiple cases within a family have been reported [8]. Low levels of fibrinogen have been found in those presumed to be heterozygous.

carriers of the defect but the evidence that heterozygous carriers can thus be detected has been questioned [9]

### *Prothrombin Deficiency*

Prothrombin deficiency as a single defect is so rare as to be worth mention only. Biggs and Douglas [10] recorded a case of acquired deficiency in a man and Quick, Pesciotta and Hussey [11] have described three patients whose defect was probably prothrombin deficiency. Two of the patients were brothers who had normal parents, four normal siblings and normal maternal and paternal grandparents. One bled for 2 months following circumcision, bruised easily, bled after tooth extractions and had a probable hemarthrosis as well as hematuria. The second had suffered from posttraumatic bleeding, gastrointestinal bleeding, easy bruising and two episodes of bleeding into his calf muscles. The latter incident responded clinically to injections of vitamin K. Both boys had prolonged prothrombin times which in the case of the second could be shortened by administration of vitamin K. Both boys had normal levels of factor V and VII. No two-stage prothrombin time test was done to confirm the prothrombin deficiency. The third patient of Quick and coworkers was a 5-year old girl of an unrelated and entirely normal family. Mixing her plasma with that of the first boy gave no shortening of the prothrombin time.

### DEFECTS IN THE EXTRINSIC THROMBOPLASTIN SYSTEM

The study of the deficiency states of the extrinsic thromboplastin system began in one of the periods of relative clarity and simplicity of blood coagulation theory. In 1935 Quick [12] devised the one stage prothrombin time test. This test was based on the classical theory of blood coagulation (Scheme 1). It consists of adding a potent tissue extract to plasma and thereafter recalcifying. Whereas the clotting time of normal plasma in the presence of  $\text{Ca}^{++}$  alone may be 120 to 180 sec, the addition of tissue extract reduces the clotting time to 12 to 15 seconds. According to the classical theory this shortening of the clotting time is due to the accelerated conversion of prothrombin to thrombin. If the clotting time is reduced in this way to a minimum and if fibrinogen is present in adequate amounts, it follows from the classical theory that variations in clotting time are caused by variation in prothrombin content. Thus the one stage prothrombin time was used as a measure of prothrombin concentration.

It is now recognized that the one stage prothrombin time test practically never gives a measure of prothrombin itself. Prothrombin in normal blood is absent from serum because it is used up during clotting. It is also adsorbed from plasma by inorganic salts such as  $\text{BaSO}_4$ ,  $\text{BaCO}_3$  and  $\text{Al(OH)}_3$ . If to a plasma sample with a long one stage prothrombin

time is added either serum or adsorbed plasma there should be no shortening of the one stage prothrombin time providing the defect is pure prothrombin deficiency. Actually the clotting of practically all pathologic samples is accelerated by addition of normal serum or adsorbed plasma. Thus the defect in the patients is not of prothrombin itself but of some other factor in the thromboplastin system.

In addition prothrombin can be measured by a method which is independent of the factors other than prothrombin such as factor VII, Stuart Prower factor, factor V, etc. This is the two stage prothrombin time test. Its use also indicates that pure prothrombin deficiency is very rare. It is performed by adding tissue thromboplastin to platelet poor plasma and recalcifying. As thrombin is formed aliquots are taken at serial times for addition to tubes containing standard amounts of fibrinogen. From a previously constructed thrombin-fibrinogen calibration curve the amount of thrombin added can be deduced and the prothrombin in the initial sample calculated.

### *Factor V Deficiency*

In 1947 Owren [13] described a female patient whose plasma had a long one-stage prothrombin time. The clotting time was reduced practically to normal by adding adsorbed (prothrombin poor) plasma. Owren showed that the corrective factor was in the fraction of adsorbed plasma which precipitated between 33 to 50 per cent saturation with  $(\text{NH}_4)_2\text{SO}_4$ . Since it differed from all previously described factors he called it factor V. The factor is very unstable on storage in the presence of oxalate. It is not adsorbed by inorganic precipitates. It disappears during clotting and is therefore not present in serum. The plasma of a patient with factor V deficiency has a long one stage prothrombin time if RVV is used as thromboplastin.

**Clinical Findings.** Patients with this defect may be severe bleeders. Nose bleeding and massive bruises are common. After trauma the bleeding may be delayed for several hours but thereafter persists until healing is advanced. Scratches and small puncture wounds do not bleed excessively. Menorrhagia is a cause of serious anemia in females. Hemarthroses are uncommon. Other cases of factor V deficiency are referred to by Biggs and Macfarlane [1].

**Genetics.** The disease may occur in either sex. Sometimes more than one member of the family is affected. Relatives of affected members may show subclinical deficiencies of factor V. In other instances no other members of the family show any abnormality. The disease may occur in either sex and may be mild or severe in degree. Although sporadic cases occur a familial pattern is more common. Consanguinity has been noted in some instances but not in others. Persons with mild cases of factor V deficiency have been found to have 1 to 5 per cent of normal levels of

factor V, severely affected patients have demonstrated no detectable levels. Congenital deficiency of factor V has been reported in association with congenital heart disease [14] syndactylism [15] epidermolysis bullosa congenitalis [16] and decreased levels of prothrombin [15] and AHC [17]. There is as yet no general agreement on the mechanism of transmission. An excellent discussion of the inheritance of factor V deficiency and of other inherited clotting disorders is given by Ratnoff [18].

### *Factor VII Deficiency*

Only a few patients with a congenital bleeding tendency attributable to factor VII deficiency have been described. The defect is suspected if there is a long one-stage prothrombin time using brain extract as thromboplastin and if the clotting time by this test is reduced to near normal by the addition of normal serum. The uncomplicated nature of the defect is confirmed in modern terms if a normal blood thromboplastin forming system is demonstrated and if the one-stage prothrombin time using RVV as thromboplastin is also normal.

Factor VII is stable on storage and is adsorbed from serum by inorganic precipitates. On electrophoresis factor VII activity is found in the  $\beta$  globulin fraction.

**Clinical Findings.** The cases of Hicks [19], Ackroyd [20] and Pitney [21] are well described. Ackroyd's patient, a male, had severe epistaxis and two hemarthroses. He bled from small cuts in a rather peculiar way. The lesions would stop bleeding normally, but bleeding would restart in 3 to 4 hr. In later life he developed gastrointestinal bleeding. An operation on an ankle caused no undue bleeding. Hicks' patient, a female, bled at the time of eruption of her first teeth. She had epistaxes in childhood and later menorrhagia. Three major operations, two for umbilical hernia and one for appendicitis, were performed without undue bleeding. Pitney's patient, also a female, bled sufficiently to require transfusion after dental extractions. She bled excessively after eight deliveries. Dental extraction following plasma transfusion therapy was uneventful.

**Genetics.** The patients described above had no history of bleeding in other members of the family.

Deficiency of factor VII has been noted both on a sporadic and on a familial basis. In a family reported by Ratnoff the deficiency appeared to be inherited as a recessive trait and the heterozygous carrier could be detected. A similar situation was reported by Quick, Pisciotto and Hussey [11] who described a 3 year-old girl who had been a severe bleeder since birth. She was found to be factor VII-deficient. Her brother, parents and maternal grandparents were clinically normal, yet all but the maternal grandmother had mildly prolonged prothrombin times and were assumed to be heterozygous for the defect. Careful studies of factor VII-deficient families by Voss [22] and Dische [22a] also suggest the factor

VII mutant gene is inherited as an autosomal recessive or intermediate gene. Thus although the disease is congenital there is no general agreement about inheritance.

### Stuart Prower Defect

This abnormality has been defined in recent years from the work of Bergigel [23] Telfer Denson and Wright [24] Hougie Barrow and Graham [25] Graham Barrow and Hougie [26] Bachman Duckert Geiger Baer and Koller [27] and Denson [28]. There appear to be no specific distinguishing clinical features corresponding to this defect. The abnormality is associated with a long one stage prothrombin time when either brain extract or RVV is used as thromboplastin. The patient's

TABLE 35-3 DIAGNOSTIC TESTS FOR AFIBRINOGENEMIA AND FOR DEFICIENCIES OF PROTHROMBIN FACTOR V FACTOR VII AND THE STUART PROWER FACTOR

| Deficiency               | Clotting time | Two stage prothrombin test | Prothrombin test |               | Correcting effect of |             |
|--------------------------|---------------|----------------------------|------------------|---------------|----------------------|-------------|
|                          |               |                            | Brain            | RVV           | Id. bed plasma       | Sum         |
| Afibrinogenemia          | No clot       | Normal                     | No clot          | No clot       | Normal clot          | No clot     |
| Prothrombin deficiency   | Long          | Abnormal                   | May be normal    | May be normal | No clot              | No clot     |
| Factor V deficiency      | Long          | Normal                     | Long             | Long          | Normal clot          | No effect   |
| Factor VII deficiency    | Normal        | Normal                     | Long             | Normal        | No effect            | Normal clot |
| Stuart Prower deficiency | Long          | Normal                     | Long             | Long          | No effect            | Normal clot |

blood also shows an abnormality in intrinsic thromboplastin formation (see below).

**Genetics.** In the case of Hougie Barrow and Graham [25] the inheritance appeared to be through an autosomal recessive gene. In this family the members heterozygous for the defect were found to have subnormal levels of Stuart Prower factor. This was true also of the family described by Bachman et al. [27]. A pedigree for Stuart Prower factor deficiency has also been recently described by Roos Arkel Verloop and Jordan [29]. This family included a consanguineous marriage which produced 12 children, 6 of whom were bleeders. These 6 had levels of Stuart Prower factor between 5 to 6 per cent. The parents & 4 of the 6 asymptomatic children and several asymptomatic relatives were found to have subnormal levels of Stuart Prower factor and were assumed to be heterozygous. One female in this family was heterozygous for both Stuart Prower defect and alcaptonuria. Thus of the three families all who were

heterozygous were asymptomatic or nearly so and those homozygous for the defect were bleeders

The properties of factors V, VII and the Stuart Prower factor related to the extrinsic thromboplastin system are compared in Table 35 2 the diagnostic tests used to distinguish between the anomalies are given in Table 35 3

#### DEFECTS OF THE INTRINSIC THROMBOPLASTIN SYSTEM

##### *Hemophilia (Hemophilia A Antihemophilic Globulin Deficiency Factor VIII Deficiency)*

Because it is the best known and most common of the clotting defects hemophilia must occupy a central point of interest in any study of inherited disorders of blood coagulation The primary defect in this disease remains unsure The contemporary interpretation is that the blood of hemophilic patients lacks AHG a substance necessary for normal coagulation A minority view is that the defect is at least in part attributable to an inhibitory substance which depresses coagulation

Most of the evidence supporting the theory that an inhibitor is responsible for the hemophilic defect is indirect Thus the clotting of diluted and undiluted plasma is compared or comparisons are made of hemophilic and normal plasma as substrates in the thromboplastin generation test [30 31] These observations do not directly delineate an inhibitor An inhibitor in hemophilic plasma should destroy or mask AHG It is true that AHG disappears rapidly from the blood of treated hemophilic patients Various estimates assess the half life of AHG after treatment at 9 to 11 hr [12 33] Thus it is possible that hemophilic blood does contain an inhibitor but until the half life of AHG in normal blood is known there can be no certainty about this At present it has certainly proved of practical value to treat hemophilic patients as if the main defect is AHG deficiency

Probably more is known of the nature of AHG than of any of the other clotting factors except  $\text{Ca}^{++}$  The substance lacking from hemophilic blood is very unstable Normal human blood collected for transfusion may lose much of its activity in 6 hr and the activity may be reduced to 30 per cent of the original in 24 hr The activity is better preserved if plasma is separated soon after collection and frozen at  $-20^\circ\text{C}$  but even at this temperature some activity is lost Activity is usually also lost during freeze drying During coagulation AHG disappears This utilization or destruction during clotting may be in part responsible for the loss of activity during the ordinary collection of blood for transfusion because in collection a minimum amount of coagulation is usual and this may be sufficient to dispose of much AHG activity Careful attention to mixing during collection seems to reduce losses [34]

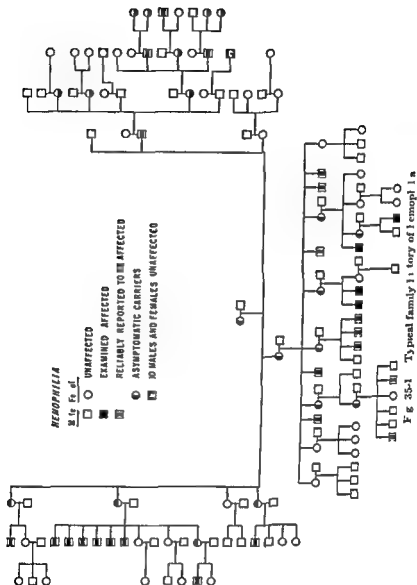

Fractionation by several different methods shows that AHG precipitates with the fibrinogen fraction of plasma. No separation of activity from human fibrinogen has been achieved without gross loss of activity. On the other hand the blood of patients with afibrinogenemia contains AHG [36]. Electrophoresis of plasma from such a patient has shown that AHG separates with the  $\beta$  globulin fraction [35].

AHG separated with fibrinogen has a narrow pH range of relative stability. It is destroyed by heating and by storage at room temperature or at 0°C. AHG is not adsorbed by inorganic precipitates such as  $\text{BaSO}_4$  and  $\text{Ca}_3(\text{PO}_4)_2$ .

**Clinical Features** The majority of hemophilic patients are males. The disease in its classical form usually declares itself in early childhood when mobility exposes the child to increasing minor trauma. Bruises disproportionate to the injury appear and disabling joint swellings may follow. The painful joint confines the patient to bed and the muscles waste. During convalescence the joints may be poorly protected and hemarthroses commonly recur. A self-perpetuating cycle of hemarthroses and wasting is initiated until by adolescence the young man may have already acquired deformed and weakened limbs. Equally disabling and often more dangerous bleeding into muscles, particularly the retroperitoneal muscles, may occur at any time. Hematuria, gastrointestinal bleeding, and epistaxis are common. Trauma such as tongue biting, small cuts, and dental extractions all give rise to troublesome and prolonged bleeding which may require transfusion.

A characteristic feature of the bleeding in hemophilic patients is that it occurs in phases. The patient in a good phase may live almost normally for months and sometimes years, surmounting many minor injuries with little inconvenience. At other times massive and apparently spontaneous bruises appear. The least injury may produce hemarthroses and further lesions appear while the patient is resting in bed to recover from the first. No consistent changes in the hemostatic mechanism have been found to account for these variations.

Another feature of hemophilic bleeding is its delayed onset. If an operation is carried out on an untreated hemophilic patient the surgeon is often pleasantly surprised by the freedom from bleeding at the time of operation. This happy state is often interrupted 6 to 8 hr later by a steady, slow, and persistent flow of blood. The surgeon returns to search for bleeding points and usually some bleeding vessel is found and ligated. Such operations are often unsuccessful and a continuing battle against a leaking sieve may continue with constant blood replacement until the much delayed healing finally happens or death occurs. Even the treated patient is susceptible to secondary hemorrhage, usually from apparently irrelevant small vessels. A single tooth socket may bleed for 4 to 6 weeks if no specific treatment is given.

This is the general clinical picture of bleeding in the severely affected patient but many hemophilic patients have a much milder version of the disease. In some the defect is disclosed only by serious injury, when unexpected bleeding stimulates a laboratory study.

**Genetics.** Hemophilia is inherited as a sex-linked recessive characteristic. A typical family record is shown in Fig. 35.1. The vast majority of families with more than one affected member show a pattern consistent with this interpretation. Exceptional families in which an occasional female has a mild bleeding tendency are often interpreted quite satisfactorily on the hypothesis that the gene is incompletely recessive.

Several cases of apparently true hemophilia in females have been reported. Three sisters who were the offspring of a consanguineous marriage in a hemophilic family were reported by Merskey [36]. They suffered from post wound and post tooth extraction bleeding, hematuria and gastrointestinal bleeding but survived childbirth and bore hemophilic sons. The female reported by Iralis [37] was born of unrelated parents who were a hemophiliac and a hemophilia carrier respectively. A recent case of sporadic AHG deficiency in a 6-year-old white female has been reported by Quick and Hussey [38]. A colony of hemophilic dogs which has been maintained at the University of North Carolina for several years has produced hemophilic females following the crossing of a hemophilic male and a carrier female [39]. Families studied often show an apparent excess of affected males [40] but this disproportion is probably due to bias in selection. No family is studied unless at least one affected male has been discovered and thus families of carriers fortunate enough to have all normal children are omitted.

Nearly half the families studied have only one affected male. There are two interpretations for this phenomenon. Either the members of the family are ignorant about affected ancestors and distant cousins or the disease has arisen anew by mutation. There are very few records sufficiently complete for certain distinction between the two possibilities. Calculations based on the life expectation of hemophilic males which is variously estimated at 16 to 22 years indicate that mutation must be fairly frequent because there is little obvious tendency for the disease to decrease.

**Christmas Disease (Hemophilia B, Factor IX Deficiency, PTC Deficiency, Hemophilia B, Factor IX Deficiency)**

This condition resembles hemophilia so closely that until recently the two abnormalities were not separated. The clinical manifestations of the two are identical as is the mode of inheritance. The conditions are distinguished because a mixture of equal parts of blood from patients with hemophilia and Christmas disease clots normally whereas the separate samples clot abnormally. The two defects are caused by defi-

*ciency of different factors [41, 43] Little is known of the nature of the factors*

**Clinical Features** Little needs to be said about the clinical features of Christmas disease since they are identical with those of hemophilia. Among the senior author's patients there are more mild cases of Christmas disease than of hemophilia. This may be a local phenomenon. A large proportion of the mildly affected patients are derived from one area. Although there is no evidence for relationship between the different families, it seems very probable that there may be common ancestors. It should not be thought on this account that Christmas disease is a milder defect than hemophilia. Some Christmas disease patients are very severely affected.

A major and unique contribution to the study of Christmas disease comes from Switzerland [43, 44]. The geographic, social and religious organization of residents in the Tenna Valley is such that relationship of a family can be traced back with considerable certainty for 11 generations. In this family 3,072 members, including 55 bleeders, have been recorded. Moor-Jankowski [43, 44] and his colleagues have brought the records of this family up to date and have personally studied 10 bleeders. All these patients had Christmas disease and Christmas factor levels of only 2.5 to 6 per cent of normal. Thus from the laboratory point of view there is great uniformity in the expression of the disease. Nonetheless there were marked differences among the different bleeders. Some were severely affected from early childhood; others had no symptoms for many years. The authors also noted a general tendency for the bleeding to be less severe with advancing years. The average life expectancy of affected members is 22 years.

**Genetics** The inheritance of Christmas disease is the same as that of hemophilia, as a sex-linked recessive. The study of the Tenna Valley family in Switzerland adds much to detailed understanding [43, 44]. This family has one case of Christmas disease that must be regarded as arising through mutation. A strange finding in this family is that female carriers have significantly more children than the normal females. In this family there is no natural tendency of the disease to die out even without mutation. The decreased number of offspring of affected males is almost exactly balanced by the increased fertility of the carriers. This record is invaluable because it provides a really good basis for testing hypotheses about inheritance in an exceptionally well recorded and studied single family.

**Surface Contact (Plasma Thromboplastin Antecedent (PTA) Deficiency and the Hageman Defect)**

The effect on clotting of contact with glass is well recognized. This phenomenon suggests that glass brings about some alteration in the

blood Recent studies have connected this phenomenon with two pathologic blood conditions PTA deficiency and the Hageman defect, [47-51] The 2 defects are currently considered together

**PTA Deficiency** In 1953 Rosenthal Dreskin and Rosenthal [46] described a new hemorrhagic state which appears to be a result of PTA deficiency and is inherited as an autosomal dominant characteristic All four patients with this syndrome that have been seen in the senior author's clinic have been Jewish This observation may have no significance but if there is a true association with Jewish ancestry the variable distribution of the disease in different parts of the world would be explicable The disease is for example common in New York but uncommon in England [40]

Patients with PTA deficiency are mostly rather mild bleeders In two female patients of the authors menorrhagia necessitated hysterectomy All have had relatively marked bruising tendency and all have bled after dental extractions or operations Occasionally more severely affected patients have had hemarthroses or muscle hematomas

**The Hageman Defect** [47] This syndrome is a strange and subversive phenomenon in the blood clotting field The eponym derived from the name of the first patient studied Patients with no hemostatic defect clinically have occasionally been found with gross laboratory abnormalities The absence of clinical defect has been confirmed in all cases by multiple uneventful surgical operations The condition therefore is readily distinguished from PTA deficiency in which there is bleeding The abnormality appears to be familial but the mode of inheritance is unclear

**Physiologic Interpretations** It is convenient to consider these two abnormalities together because the laboratory results are similar Blood samples from patients with either syndrome may have a long clotting time and an abnormal prothrombin consumption In both abnormalities the thromboplastin generation test shows an unusual pattern but the results are often abnormal only if both serum and adsorbed plasma are derived from the patient In some cases a slight apparent deficiency of Christmas factor occurs In others the thromboplastin generation test gives entirely normal results

Conflicting results have emerged from many aspects of laboratory testing in these cases Fractionation work has not revealed a specific PTA fraction with any clear definition Samples initially apparently deficient in PTA factor may approach normality on storage Mixture experiments may give confusing results samples from the same patient may be considered to show PTA deficiency or Hageman defect on different occasions Many of these difficulties can be attributed to the nature of the underlying defect

In both these conditions there appears to be a defect in ability to react

to glass surface. Thus depending on the degree of glass exposure of samples being tested the results will vary. From the observations of Biggs et al. [45] it seems that if samples are collected in silicone treated apparatus a glass exposed PTA deficient sample will correct the defect of a silicone-stored sample from a Hageman defect patient but will not correct the abnormality of a silicone-collected PTA deficient specimen. In the reverse experiment a glass-exposed sample from a Hageman defect patient will not correct the abnormality of a silicone-collected PTA deficient specimen. These experiments suggest that the Hageman factor is the one which reacts to contact with glass and that the product of this activation reacts with the PTA factor.

The apparent Christmas factor deficiency which may be encountered in these cases is probably due to slow activation of a precursor of the Christmas factor. If a mixture of PTA deficient and Christmas disease serums is allowed to stand before testing the abnormality may disappear [45]. It presumably takes some time for the PTA factor in the Christmas disease serum to activate the precursor of Christmas factor in the PTA deficient serum.

#### MULTIPLE FACTOR DEFECTS

##### *von Willebrand's Disease*

This disease would not previously have been included among the constitutional coagulation defects because the main abnormality has always been considered a failure of capillary function. It is now recognized that many patients with this syndrome are also deficient in AHG. A new name for this disease, vascular hemophilia, has recently gained favor but since the original family described by von Willebrand [52] had AHG deficiency there would seem to be little ground for multiplication of nomenclature.

In the more severely affected subjects there is evidence for a dual defect, one of the clotting mechanism and the other of the capillaries. Severely affected patients often have a level of AHG which is in the range seen in the blood in mild hemophilia but this association of defects is by no means found in all cases. Nothing is known of the intimate nature of the capillary defect. One possible explanation is that abnormality of the small vessels produces AHG deficiency when the vessel anomaly is sufficiently severe. Perhaps such vessels lead to rapid utilization of AHG, or perhaps AHG is made in the normal vascular endothelium.

**Clinical Features.** Patients with this condition bruise easily. They have frequent and often severe epistaxes. Females may have severe menorrhagia which may require transfusion. There may be bleeding from the gums and there is bleeding always after dental extraction. Small cuts bleed freely but the blood flow is stopped easily and usually permanently by pressure. Surgery has proved surprisingly uneventful. There is

usually some excessive bleeding, but the persistent and uncontrollable bleeding of the hemophilic patient is absent.

**Genetics** The condition is inherited as an autosomal dominant trait. A typical family tree is given in Fig. 35.2. In mildly affected patients the level of AHG may be normal. Nilsson, Blombäck and Francken [53] record a family in which a low AHG level occurred in association with von Willebrand's disease. Study of clinically unaffected members of the

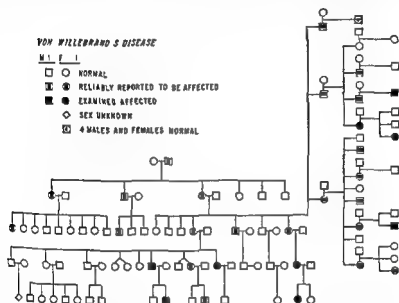

Fig. 35.2. Family history illustrating the inheritance in von Willebrand's disease.

family showed that some of them had low AHG levels. There is thus the possibility that the two features (AHG level and capillary function) are inherited separately and that the combination gives rise to severe examples of disease. Such severely affected patients are more frequently studied than less serious bleeders. This possibility was suggested by Pitney [54]. If this is the case, this variety of AHG deficiency is inherited as an autosomal dominant characteristic.

## *Dicoumarol Intoxication*

A most informative and relevant abnormality (although not an inherited disorder) is that caused by the dicoumarol group of drugs. The type of clotting anomaly depends upon the duration of treatment and to some extent on the drug used. A patient who has been treated for more than a week and whose level of prothrombin time is within the therapeutic range usually shows a pattern as follows:

| <i>Factor</i>        | <i>Percentage of Normal</i> |
|----------------------|-----------------------------|
| Prothrombin          | 40-70                       |
| Factor VII           | 5-10                        |
| Christmas factor     | 10-50                       |
| Stuart Prower factor | 10-50                       |

In addition there may be deficiency of yet another coagulation factor, which is at present ill defined. The level of Christmas factor and Stuart Prower factor depends upon the extent of the defect. Exactly the same pattern is found in vitamin K deficiency and in some congenital cases with multiple clotting defects [55-56]. These observations suggest that there must be some common pathway for the manufacture of these factors or that the defect represents an interference with some factor on which all the others depend. The blood of these patients may show confusing results with conventional tests. The clotting time is usually normal because none of the factors is reduced to a rate-limiting degree. Thromboplastin generation is often quite abnormal when the patient's serum replaces normal serum. Mixture experiments may give confusing results unless specifically defective samples are used.

Other reported anomalies include combined deficiency of AHG and factor V [17-58] or factor VII and Stuart Prower factor [29].

## LABORATORY DIAGNOSIS OF CLOTTING FACTOR DEFECTS

The clinical tests of clotting for the most part relate to measurements of the components of the internal thromboplastin system. Some of these will be reviewed here in order to indicate the extent of the current experimental limitations in the coagulation field.

### *Clotting Time*

In this test a measured quantity of blood is put into a glass tube and the time until solidification is complete is recorded. The details of technique vary from center to center. Usually four tests are done and average results reported. The test is entirely nonspecific; any defect at any stage may influence the results. The test has been modified for quantitative measurement of a specific factor by taking the blood of a patient with a known defect, e.g., hemophilia, and adding to this the blood of another patient. If the clotting time of the mixture is shorter than that of the standard patient then the undiagnosed patient has some other defect. By adding different known proportions some quantitative estimate can be made. The use of the test in this way is open to much criticism and in practice is most inaccurate. The test will for example record normal results with as little as 1 to 5 per cent of AHG in a sample of hemophilic blood. Moreover the practice rests on the assumption that the defect in the standard plasma is accurately known. This is certainly not often

true For example before the recognition of Christmas disease the random selection of a hemophilic plasma as a standard would not infrequently have resulted in the choice of a sample from a patient with Christmas disease

### *Prothrombin Consumption*

During normal coagulation prothrombin is converted to thrombin and little remains in the serum If the intrinsic plasma thromboplastin forming system is defective then much prothrombin is found in serum The test consists in making an empirical assessment of the relative amount of prothrombin present in the serum The test is much more sensitive than the clotting time to minor deviations from normal The test is in itself quite nonspecific It gives no information about what is wrong but merely records abnormality It has been used with standard blood samples to define new defects in the manner described for the clotting time test

### *Thromboplastin Generation*

In this test reagents prepared from normal plasma when mixed together can be shown to generate a powerful thromboplastic agent in the presence of calcium ions [62] The reagents required are  $\text{Al}(\text{OH})_3$  or  $\text{BaSO}_4$  treated plasma serum and platelets To analyze the reactions involved it is necessary to consider the factors contained in this complicated mixture

**$\text{Al}(\text{OH})_3$  or  $\text{BaSO}_4$  treated Plasma** This contains AHG and factor V Experiments in which one or the other of these factors is excluded from the system have shown that both are essential

**Serum** Serum contains factor VII Christmas factor and the Stuart Prower factor Experiments this time with serum from patients who lack one or the other of these factors have shown that Christmas factor and the Stuart Prower factor are required but that factor VIII is not essential

**Platelets** Platelets can be replaced in the thromboplastin generation test by preparations of brain phospholipids made according to the method of Folch [63] With this information there have been many attempts to identify a chemically definable fraction as the one active substance Some workers have found that attempts at purification are accompanied by loss of activity and have concluded that a single active substance cannot be located [64] Others have implicated phosphatidylethanolamine [65-66] and phosphatidylserine [66-68] as the active compound Recent work suggests that several phosphatides may be required [68] a suggestion which would account for the loss of over all activity during purification

The thromboplastin generation test is used as a diagnostic aid In diagnosis it is used to distinguish between hemophilia and Christmas disease by making mixture reagents from normal blood and a patient's blood The general plan of such a diagnostic test is shown in Table 35-4 This test does not require a standard abnormal sample to define the

abnormality but it does rest on the assumption (probably false) that all the main coagulation factors are known

TABLE 35.4 THROMBOPLASTIN GENERATION TEST USED FOR DIAGNOSIS OF HEMOPHILIA AND CHRISTMAS DISEASE IN PATIENTS WHOSE PLASMA HAS A NORMAL ONE STAGE PROTHROMBIN TIME

| Source of $Al(OH)_3$<br>treated plasma | Source of<br>serum | Source of<br>platelets or<br>phospholipid | Results      |                      |
|--|--------------------|---|--------------|----------------------|
|  |                    |   | Hemophilia   | Christmas<br>disease |
| Normal                                 | Normal             | Normal                                    | Control test |                      |
| Normal                                 | Patient            | Normal                                    | Normal       | Abnormal             |
| Patient                                | Normal             | Normal                                    | Abnormal     | Normal               |
| Patient                                | Patient            | Normal                                    | Abnormal     | Abnormal             |

Both factor V and Stuart Prower factors are required for blood thromboplastin formation deficiencies of these two factors are distinguished by the thromboplastin generation test as shown in Table 35.5 In tests using these samples phospholipid [69] should be used in place of platelets because platelets adsorb factor V from normal plasma and the use of normal platelets may mask the defect

TABLE 35.5 THROMBOPLASTIN GENERATION TEST RESULTS FOR PATIENTS WITH FACTOR V OR STUART-PROWER DEFECT

| Source of $Al(OH)_3$<br>treated plasma | Source of serum | Results                |                         |
|--|-----------------|------------------------|-------------------------|
|  |                 | Factor V<br>deficiency | Stuart Prower<br>defect |
| Normal                                 | Normal          | Control test           |                         |
| Normal                                 | Patient         | Normal                 | Abnormal                |
| Patient                                | Normal          | Abnormal               | Normal                  |
| Patient                                | Patient         | Abnormal               | Abnormal                |

The one-stage prothrombin time test carried out on the plasma of these patients gives abnormal results

Factor VII deficiency causes no blood thromboplastin defect thus clotting time prothrombin consumption index and thromboplastin generation test all give normal results

The thromboplastin generation test can also be adapted to study the physiology of blood thromboplastin formation Thus Biggs Douglas and Macfarlane [70] showed that if AHG serum and calcium are in

cubated together an active intermediate product of coagulation is formed. The interaction of this product with platelets produces an active particulate substance which can be sedimented by centrifuging [71]. Biggs and Bidwell [72] showed that the final product of thromboplastin formation is unstable but can be reactivated by the addition of factor V. Hougie and his coworkers [25] have shown that the Stuart Prower factor is probably concerned together with Christmas factor in reaction with AHG.

*Modification of the Thromboplastin Generation Test for the Assay of AHG [32]*

A method for the quantitative assay of AHG can be devised if it is assumed that AHG affects quantitatively the yield of active thromboplastin and that preparations which give the same minimum clotting time by this test have the same activity. Using this method it has been possible to predict from blood levels of AHG the severity of bleeding to be expected. Thus if a patient has more than 5 per cent of a normal level of AHG he will be very mildly affected. Again if levels below 25 per cent of normal are achieved by therapy the bleeding will not be controlled adequately after surgical treatment. From these practical results it is reasonable to assume that the test gives some measure of the hemophilic defect [32]. It should be emphasized that a common sense assessment of success or failure in practice is the only way of judging whether or not assumptions about a quantitative method are reasonable.

The election of techniques described is not comprehensive nor are they necessarily the best tests. The main purpose of this review is to bring into focus the limitations of this whole field of study. In Table 35.6 the methods have been related to the theory of blood coagulation. It will be seen that even assays for specific factors may be affected by many variables and that the factors which affect the cruder screening tests such as the clotting time and prothrombin consumption tests, are innumerable. In the more specific assays attempts are made to eliminate undesirable variables by using standard plasma samples or by supplying irrelevant factors at high concentration. Despite this care most coagulation tests rank in accuracy and reliability more with rather crude biologic assays than with chemical analyses.

## BLOOD COAGULATION AND HEMOSTASIS

There now remains the question of the relationship between hemostasis and blood coagulation. The conventional view of hemostasis [73] is of a dual mechanism involving platelet, capillary and arteriolar function on the one hand and blood coagulation on the other. A small injury ceases to bleed because the vessels are contracted and plugged by plate

TABLE 3.6 APPROXIMATE RELATIONSHIP OF TESTS USED IN THE DIAGNOSIS OF COAGULATION DEFECTS TO THE STAGES OF BLOOD COAGULATION WHICH AFFECT THEM

| Stages of the extrinsic thromboplastin system using mammalian tissue extract (thromboplastin)   | Tests applicable to the extrinsic system  | Tests applicable to both extrinsic and intrinsic systems  | Tests applicable to the intrinsic system  | Stages of the intrinsic thromboplastin system  |

lets. After a lapse of time the vessels relax and bleeding is not resumed because the vascular lumen is filled by clot. For larger injuries vascular contraction cannot stem the flow and ligature or pressure must arrest the bleeding and allow time for blood coagulation. There is no reason to suppose that this view is not substantially correct. A detailed analysis of bleeding associated with single-factor defects may suggest whether or not hemostasis may be achieved by one of the several mechanisms available and whether or not the mechanisms are different in different tissues. A study of some inconsistencies may also reveal new fields for exploration.

By comparing factor VII deficiency with hemophilia or Christmas disease the relative importance of the intrinsic and extrinsic thromboplastin systems may be assessed. The first point of interest is that two of the factor VII-deficient patients described had operations with no very excessive bleeding, whereas in hemophilic patients operations are notoriously dangerous. This observation if confirmed for other cases of factor VII deficiency suggests that the intrinsic (blood) thromboplastin system is the more important for sustained hemostasis. This conclusion is also borne out by a more detailed study of hemophilic bleeding. Hemophilic patients are very liable to secondary hemorrhage. Even a treated patient will start to bleed if the treatment is inadequately maintained. One large dose of AHG to a hemophilic patient will stop bleeding for 24 to 48 hr. This observation suggests that normal hemostasis involves the continued renewal of clot and that the intrinsic thromboplastin mechanism is of primary importance for the process.

If bleeding at different sites is considered it becomes clear that hemarthroses are associated with severe hemostatic defects whatever the cause. Hemarthroses are usually linked with hemophilia because hemophilia is the most common serious hemostatic defect but mildly affected hemophilic patients do not have hemarthroses and severely affected patients with extrinsic thromboplastin defects do. Hematuria can occur in any defect. Persistent oozing from small skin injuries and from the gums is predominantly a feature of capillary abnormalities. Deep muscle hematomas are much more common in hemophilia than in any other disease. It may be that the muscle tissue is a poor source of thromboplastin and that muscle hemostasis normally depends very little on the extrinsic system. The peculiar observation of Ackroyd that a factor VII-deficient patient tended to have recurrent hemorrhage from trivial superficial injuries and the capillary defect (indicated by a long bleeding time) which may occur in patients with vitamin K deficiency and after excessive dosage of dicoumarol suggest that the extrinsic thromboplastin system may have something to do with the maintenance of capillary function.

There are certain interesting inconsistencies between laboratory results and hemostatic function. The most obvious of these is the absence of

abnormal bleeding in patients with the Hageman defect. Workers are so familiar with the usual dire significance of a long clotting time that a syndrome in which abnormality in this test does not herald a severe hemostatic defect is a surprise. The only reasonable interpretation is that in the body the stimulus initiating coagulation is not a surface which resembles glass in any way. The glass surface may perhaps by pass or replace the natural stimulus to clotting. The failure of the glass mechanism would not necessarily be associated with any in vitro hemostatic defect. One might reason that it should be possible to find patients who have clinical hemorrhagic states but in whom the natural stimulus to clotting is defective. Such patients should have no clotting abnormality if their blood is tested in glass tubes. Coagulation specialists often encounter patients who give a definite history of bleeding but whose laboratory tests are negative. Some of these cases may have the postulated defect but proof is at present impossible.

Another and much more fundamental difficulty concerns the coagulation defect in afibrinogenemic patients. The bleeding tendency in these patients should be the most severe of all. In fact the bleeding is usually less pronounced than in a severely affected hemophilic patient. This is a disturbing paradox to which at present there is no solution. It is difficult to understand why slow and defective clotting should be more dangerous than no clotting at all. Sooner or later this problem must be faced. It is possible for example that AHG is an essential component for healing and that one of the main defects in hemophilia is a delay in healing. It is also possible that the congenital absence of fibrinogen stimulates a particularly good mechanism of vascular contraction and platelet agglutination and that this mechanism can to some extent replace the functions of coagulation.

Another perplexing problem concerns the different types of bleeding in patients with hemophilia and von Willebrand's disease. Although patients with von Willebrand's disease may have low AHG levels they do not bleed in the same way as hemophilic patient. The patients with von Willebrand's disease have epistaxis and the females have menorrhagia; they bruise easily but do not have massive muscle hematomas. Bleeding after dental extraction is immediate and readily controlled by pressure. Postoperative hemorrhage is rarely disastrous. The characteristic hemophilic hemorrhage is a slow persistent ooze not controlled by pressure. Hemophilic patients do have deep muscle hematomas and postoperative bleeding is often disastrous. There is at present no explanation for this discrepancy. It is possible of course that the AHG deficiency of von Willebrand's disease is due to a rapid utilization of AHG by poor capillaries and it is also possible that hemophilic patients often have some as yet ill defined inhibitory factor which reinforces the underlying AHG defect.

## SUMMARY

1 Interpreted as molecular diseases the coagulation defects are sadly lacking in definition. There is no biochemical definition by current techniques but only alignment with empirical schemata. There is also no definition from clinical or metabolic features of the patients.

2 In due course it may be possible to interpret coagulation defects in terms of deficiency of definite chemical species or reaction sequences. At present no single chemical substance (except calcium) has been identified. The present study of the role of phospholipids is of particular importance; by continuing in this direction it may become possible for the first time to define a coagulation factor chemically.

3 Complex events precede the formation of fibrin from fibrinogen. This reaction is controlled by thrombin which in turn is derived from prothrombin by the combined action of calcium and plasma thromboplastin or prothrombinase.

4 Prothrombinase activity resides either in an external system composed of tissue extract and calcium or in an internal system derived from the platelets, plasma coagulation factors and  $\text{Ca}^{++}$ . Each of these prothrombinase systems is complex in itself and contains several factors necessary for prothrombinase activity.

5 Clinical hereditary coagulation defects may result from deficiency of any one of the several components of the clotting mechanism. Fibrinogenemia is one of these with mild clinical implications. It is an autosomal recessive disorder.

6 Defects in the extrinsic thromboplastin system include (a) factor V deficiency disease which may be a severe bleeding disorder and which has an uncertain inheritance pattern; (b) factor VII deficiency also with severe bleeding tendency and probably autosomal recessive inheritance; (c) Stuart Prower defect a disorder with clinical findings identical to those of factor VII deficiency and with autosomal recessive inheritance.

7 Defects of the intrinsic thromboplastin system include (a) classical hemophilia which is a result of hereditary absence of the AHG component and has recessive sex-linked inheritance; (b) Christmas disease resulting from deficiency of plasma thromboplastin component indistinguishable clinically from classical hemophilia and having also a sex-linked recessive inheritance; (c) Hageman factor defect which has no clinical manifestations; and (d) plasma thromboplastin antecedent a mild bleeding disorder with an uncertain inheritance pattern.

8 Occasionally multiple factor defects are encountered. Among these is von Willebrand's disease which may appear as a dual defect of the capillaries and the clotting mechanism. The bleeding tendency is mild. It is usually inherited as an autosomal dominant trait.

9 No clarity has emerged from the study of blood coagulation factors

in relation to hemostasis but the shadowy outline emerging suggests that hemostasis may be achieved through several partly independent but connected mechanisms. If one mechanism fails, others may in part replace it.

10 At present it must be admitted that there is an atmosphere of fantasy and improbability about the whole subject. Future workers may well view the present elaborate superstructure of hypothetical factors and hypothetically interpreted tests with the tolerance which we now afford to those who thought blood letting was a valuable therapeutic agency.

## Chapter 36

# Familial Hypophosphatemia and Vitamin D-resistant Rickets

---

*T Franklin Williams Robert H Winters and Charles H Burnett*

### DEFINITION

Familial hypophosphatemia and vitamin D-resistant rickets may be defined as a specific disorder characterized by (1) hypophosphatemia associated with decreased renal tubular reabsorption of inorganic phosphate (2) familial occurrence the mode of inheritance being most probably sex linked dominant (3) the presence in some but not all affected persons of rickets or osteomalacia which does not respond to the usual doses of vitamin D (4) the absence of other related abnormalities

This definition excludes conditions which may share the same clinical or physiologic features or biochemical defects such as sporadic (non familial) vitamin D-resistant rickets associated with hypophosphatemia and familial vitamin D-resistant rickets associated with normal or high serum concentrations of inorganic phosphate Patients with multiple renal tubular defects such as the Fanconi syndrome or renal tubular acidosis appear to have similar but more extensive abnormalities

Regarding the limited group defined above as a separate entity has several advantages The clear-cut genetic pattern allows one to identify a substantial number of persons who presumably have the same fundamental physiologic and biochemical abnormality Furthermore the presence of a single gross defect in renal tubular function simplifies the analysis Clarification of a single aberrant mechanism is a logical step in the study of the multiple defects of related conditions

### HISTORICAL DEVELOPMENT

The growth of understanding of this disorder has proceeded along clinical physiologic and genetic pathways Rickets which failed to

respond to usual doses of vitamin D was recognized only after vitamin D-deficiency rickets had been largely eliminated by prophylaxis. In such a patient Albright, Butler and Bloomberg [1] in 1937 first showed that very large doses of vitamin D would bring about healing of the rickets. That the hypophosphatemia was due either primarily or secondarily to decreased renal tubular reabsorption of phosphate was first recognized by Robertson, Harris and McCune [2] in 1942.

The first description of familial occurrence of vitamin D-resistant rickets with hypophosphatemia was in 1941 by Christensen [3] who reported a mother and her son and daughter with typical features of the disease. Earlier instances of familial occurrence are probable [4]. On the basis of skeletal manifestations several workers proposed an autosomal dominant mode of inheritance with variable penetrance [5, 6]. However, Winters and his collaborators [7-9] were able to show that the occurrence of hypophosphatemia in involved families follows a sex-linked dominant mode of inheritance with virtually complete penetrance. They worked on the assumption that the basic disorder lies in the abnormal renal excretion of inorganic phosphate with resulting hypophosphatemia and that the rickets and osteomalacia are secondary manifestations.

## CLINICAL AND RADIOLOGIC FINDINGS

The mildest abnormality is purely biochemical. This is hypophosphatemia (see below under Hypophosphatemia for criteria for hypophosphatemia) without clinical manifestations other than a slight decrease in height when compared with normophosphatemic siblings. This is the most common finding in kindreds with the disorder [7-9].

In hypophosphatemic adults the varying degrees of deformities due to rickets in childhood constitute more serious disturbances. These include bowing of the legs and shortening of stature usually without evidence of continuing active bone disease. A few affected adults have evidence of continuing osteomalacia as judged by the presence of pseudofractures and an elevated serum alkaline phosphatase level. These latter changes revert towards normal upon administration of massive doses of vitamin D.

In affected children with rickets the disease is usually first recognized when the child begins to walk, but the history or x-ray examination often reveals abnormalities dating to the first year of life such as deformities of the skull, late dentition and 'sitting' deformities of the legs. These children usually have received prophylactic doses of vitamin D and have failed to respond to the doses given to cure what was initially thought to be vitamin D-deficiency rickets. Healing of the active rickets occurs upon treatment with very large doses of vitamin D (usually 100,000 I.U. or more per day). Permanent deformities and shortened stature often are present. In adults and in children the use of the massive doses of vitamin D required for healing frequently results in the appearance of

vitamin D intoxication with discontinuance of the vitamin the rickets usually becomes active again. Thus vitamin D-resistant rickets differs clinically from vitamin D-deficiency rickets both in the hundredfold greater dose required to induce healing and in the fact that a permanent cure is rarely achieved until growth is completed.

Among family members with hypophosphatemia females show considerably less bone disease than males. Very few patients have the

Fig 36-1 Anteroposterior view of the knees of a 4-year-old boy (VI) of 1 kindred of Winters et al [51] showing marked rachitic changes with early healing and lateral curvature of femora and tibiae

muscular weakness and atony that are such prominent and frequent features of vitamin D-deficiency rickets. Only one case of familial vitamin D-resistant rickets with findings suggestive of tetany has been reported [10]. There has been no steatorrhea, liver disease, or renal disease other than the specific abnormalities discussed in the next section. Cranioostenosis and convulsions in infancy have occurred often enough in association with familial vitamin D-resistant rickets to raise the possibility of relationships between them.

The radiologic findings in this syndrome are the same as those seen in rickets or osteomalacia from other causes. In children with rickets the typical changes in the epiphyseal regions of the long bones are the most common and characteristic findings (Figs 36-1, 36-2). Fractures and

Fig 36-2 View of the knees of same patient as that in Fig 36-1 after 3 years of treatment with large doses of vitamin D. Healing is still not complete

Fig 36-3 Anteroposterior view of the humerus of a 58-year-old man (IV-5 of the E kindred of Winters et al [8]) showing coarse trabeculation and a bony protuberance at the site of insertion of the deltoid muscle

pseudofractures and deformities of the skull thorax and long bones are also seen. Additional changes which are occasionally present are similar to those seen in certain osteochondrodystrophies such as coarsened trabecular patterns in long bones, cystic appearing areas in metaphyses and epiphyses, and shortening and broadening of the long bones. Occasionally abnormal bony protuberances appear at the site of major

Fig 36-4 Anteroposterior view of femur of a 41 year-old man (V 10 of E kindred of Winters et al [8]). Note coxa vara, lateral curvature of femur, and pseudofracture of the femoral neck.

muscular attachments and around the joints (Fig 36-3). In adults post-rachitic deformities and rarely pseudofractures occur (Fig 36-4).

Table 36-1 summarizes schematically the principal clinical findings of this disorder. The original reports of familial instances may be consulted for additional details [3: 5-29a].

## HYPOPHOSPHATEMIA AND THE ABNORMALITY IN RENAL EXCRETION OF PHOSPHATE

### HYPOPHOSPHATEMIA

The significant place which a low serum concentration of inorganic phosphate occupies in this disease is highlighted by two lines of evidence

TABLE 36-1 SUMMARY OF FINDINGS IN FAMILIAL HYPOPHOSPHATEMIA AND VITAMIN D RESISTANT RICKETS

| Type of hypophosphatemia  | Age at onset, yr | Clinical and radiologic abnormalities   | Concentration in serum |                     |                         | Other observations   |
|---|------------------|---|------------------------|---------------------|-------------------------|--|
|   |                  |   | Calcium                | Inorganic phosphate | Alkaline phosphatase    |  |
| 1 Asymptomatic hypophosphatemia                                       | Under 1          | Slightly shortened stature  | Normal                 | Low                 | Normal                  | No other abnormalities   |
| 2 Hypophosphatemia in adults with inactive posttraumatic deformities  | Under 1          | Latent (and usually anterior) bowing of legs, shortened stature, occasionally coarsened trabeculation, rarefied areas | Normal                 | Low                 | Normal or slightly high | More frequent anion gap, hypophosphatemic males                                  |
| 3 Hypophosphatemia in adults with deformities and active osteomalacia | Under 1          | Same as for (2) plus pseudo fractures   | Normal                 | Low                 | Slightly high           |  |
| 4 Hypophosphatemia with resistant rickets in child or adult           | Under 1          | Active rickets, occasionally coarsened trabeculation, shortened stature   | Normal or slightly low | Low                 | High                    | More severe in affected males, craniostenosis and convulsions in a few instances |

(1) almost all cases which would be called resistant rickets on other grounds have also had hypophosphatemia (the normal values for serum phosphorus reported by Lernerloth et al [23] in cases with similar clinical features may have been obtained during treatment or those cases may represent a slightly different entity) (2) the probable mode of inheritance has been best revealed by using hypophosphatemia as the discriminant (see below)

In designating a person as hypophosphatemic, due allowance must be made for the normal changes in serum phosphorus with age and for differences between the sexes. This was done by Winters and coworkers [7-9] who expressed mathematically and graphically and with limits of statistical confidence the relationship between serum phosphorus and age for each sex for a large number of observations on normal persons [30]

The age of first appearance of hypophosphatemia has not yet been determined. The present authors have found the detection of hypophosphatemia in a young infant to be difficult even though at a later time the child proves to have the disease. Whether or not this indicates some fundamental age conditioned difference in renal excretion of phosphate or other factors controlling the serum phosphorus in affected individuals is not known.

Among hypophosphatemic individuals in affected families females have slightly higher values for serum phosphorus than males in the same family at all ages.

The alkaline phosphatase level is elevated in affected persons with active rickets or osteomalacia. Treatment with sufficient vitamin D to produce healing of the rickets is accompanied by a return of the alkaline phosphatase to or toward normal. In some instances the serum phosphorus level has risen with treatment but healing has also been observed with no significant rise in phosphate concentration (see Treatment further on).

Other related serum chemical determinations usually give normal results. The serum calcium concentration is normal or rarely slightly low. Serum total protein, albumin and globulin fractions, urea or non protein nitrogen, amino acids, sodium, potassium, chloride, carbon dioxide content and pH are uniformly normal.

In every instance in which it has been studied the hypophosphatemia has been associated with increased renal excretion and decreased renal tubular reabsorption of phosphate. This renal abnormality whatever its origin appears to be the principal cause of the hypophosphatemia. Discussion of this abnormal function requires description of the normal mechanism of phosphate excretion and of factors known to influence it.

## NORMAL MECHANISM FOR RENAL EXCRETION OF PHOSPHATE

The following points have been clearly established

1 At plasma concentrations up to at least 17 mg per 100 ml all the inorganic phosphate of the plasma is ultrafiltrable [31-33]. The phosphate enters the glomerular fluid at virtually the same concentration as that in the plasma [34-35]. Accordingly, the amount of phosphate filtered per unit time is the product of the glomerular filtration rate (as measured by clearance of an agent like inulin) and the plasma concentration of phosphate.

2 In man and dog the net effect of tubular action on glomerular fluid is reabsorption of phosphate: the amount of phosphate excreted is normally only a small fraction of that filtered. The evidence obtained in the dog by Pitts et al. [36] using the stop flow technique suggests that reabsorption of phosphate occurs in the proximal tubule. Only in rare instances [37-40] has evidence for net tubular secretion of inorganic phosphate in man been found. Net tubular secretion of inorganic phosphate has been demonstrated in chickens [41] in cats after infusion of organic phosphates [42] and probably in acidotic dogs [42a].

3 In man and the normal dog a maximal rate of net tubular reabsorption of inorganic phosphate ( $Tm_p$ ) is readily demonstrated. If the concentration of phosphate in the plasma is raised progressively the calculated rate of net reabsorption of phosphate (phosphate filtered minus phosphate excreted) reaches a constant value and further increments in filtered phosphate are accompanied by a corresponding increase in excreted phosphate. When measured under standardized conditions the values for  $Tm_p$  are reasonably constant in normal individuals on normal diets. Most reported normal values for  $Tm_p$  for children and adults are between 120 and 150  $\mu$ m phosphate reabsorbed per 100 ml glomerular filtrate although a few supposedly normal individuals have had values as low as 80  $\mu$ m per 100 ml glomerular filtrate [43-49]. These results do not exclude tubular secretion of phosphate but they do indicate that if secretion occurs it must be at a constant rate and must be unaffected by progressive rises in plasma phosphate concentration.

The  $Tm_p$  is the most meaningful physiologic measurement of renal tubular activity in any consideration of phosphate excretion. Other appraisals of the renal mechanism for excretion of phosphate have frequently been used. Among these are the renal clearance of phosphate ( $C_{PO}$  = excreted phosphate/serum phosphorus) the percentage of filtered phosphate that is reabsorbed (%TRP) and the fraction of filtered phosphate that is not reabsorbed (=  $C_{PO}/C_I$ ). These estimations are made without loading the excretory mechanism with phosphate. Since these three calculations are all influenced by the serum phosphate concentration as well as by glomerular and tubular function direct interpretation of

tubular activity from them is extremely difficult. Their use has at times led to confusing and erroneous views. In patient IV 5 of Table 36-3 for example before phosphate loading the  $C_{\text{Po}}$  was 13 ml per min and the %TRP was 87 both within the range of 'normal' yet the  $Tm_{\text{P}}$  was distinctly low. (This patient had normal intake of phosphate prior to the  $\Pi$  measurements; an unusually high or low intake will be reflected in changes in  $C_{\text{Po}}$ , %TRP and  $C_{\text{Po}}/C_{\text{I}}$  because of the effect on serum phosphate concentration without any change necessarily in tubular function.) As suggested by Lambert et al [46] and Milne et al [50] care should be taken to compare these calculated values with those obtained for normal subjects at the same level of serum phosphorus. When the glomerular filtration rate is normal (see below) it may be possible thus to separate abnormal from normal phosphate excretory patterns. In the example cited above a  $C_{\text{Po}}$  of 13 ml per min is actually probably high for a serum phosphorus of 2.4 mg per 100 ml.

In the presence of renal disease with significant reduction in glomerular filtration rate the (unloaded) tubular reabsorption of phosphate is usually depressed out of proportion to the decrease in glomerular filtration [51]. It is clear that interpretations of tubular reabsorption of phosphate in other abnormal states cannot be made when there is significant concomitant reduction of glomerular filtration. This change in tubular reabsorption may conceivably be related to increased parathyroid function (see Hormonal Factors below).

#### FACTORS KNOWN OR THOUGHT TO INFLUENCE THE NORMAL MECHANISM FOR EXCRETION OF PHOSPHATE

##### *Possible Effects of Acute Changes in Glomerular Filtration Rate*

In the dog changing the glomerular filtration rate—by varying the protein intake—causes no change in  $Tm_{\text{P}}$  [52]. Evidence in man is less clear-cut partly because of the difficulty of producing large changes in glomerular filtration rate [45–47]. Gross abnormalities of tubular reabsorption as seen for example in hyperparathyroidism and familial hypophosphatemia may occur without any evidence of changes in glomerular filtration rate [8, 49–53].

##### *Hormonal Factors*

Intramuscular administration of extracts of bovine parathyroid glands over several days to normal subjects and hypoparathyroid patients produces an increased excretion of phosphate, a fall in serum phosphorus and a fall in  $Tm_{\text{P}}$  [54]. Patients with proved hyperparathyroidism have low values for  $Tm_{\text{P}}$  and the  $Tm_{\text{P}}$  eventually returns to normal or nearly normal after removal of the overactive parathyroid tissue [49–53, 55], provided there has been no permanent renal damage. Thus there is little

## NORMAL MECHANISM FOR RENAL EXCRETION OF PHOSPHATE

The following points have been clearly established

1 At plasma concentrations up to at least 17 mg per 100 ml all the inorganic phosphate of the plasma is ultrafiltrable [31-33] The phosphate enters the glomerular fluid at virtually the same concentration as that in the plasma [34, 35] Accordingly, the amount of phosphate filtered per unit time is the product of the glomerular filtration rate (as measured by clearance of an agent like inulin) and the plasma concentration of phosphate

2 In man and dog the net effect of tubular action on glomerular fluid reabsorption of phosphate the amount of phosphate excreted is normally only a small fraction of that filtered The evidence obtained in the dog by Pitts et al [36] using the stop-flow technique suggests that reabsorption of phosphate occurs in the proximal tubule Only in rare instances [37-40] has evidence for net tubular secretion of inorganic phosphate in man been found Net tubular secretion of inorganic phosphate has been demonstrated in chickens [41] in cats after infusion of organic phosphates [42] and probably in acidotic dogs [42a]

3 In man and the normal dog a maximal rate of net tubular reabsorption of inorganic phosphate ( $Tm_P$ ) is readily demonstrated If the concentration of phosphate in the plasma is raised progressively the calculated rate of net reabsorption of phosphate (phosphate filtered minus phosphate excreted) reaches a constant value and further increments in filtered phosphate are accompanied by a corresponding increase in excreted phosphate When measured under standardized conditions the values for  $Tm_P$  are reasonably constant in normal individuals on normal diets Most reported normal values for  $Tm_P$  for children and adults are between 120 and 150  $\mu$ m phosphate reabsorbed per 100 ml glomerular filtrate although a few supposedly normal individuals have had values as low as 80  $\mu$ m per 100 ml glomerular filtrate [43-49] These results do not exclude tubular secretion of phosphate but they do indicate that if secretion occurs it must be at a constant rate and must be unaffected by progressive rises in plasma phosphate concentration

The  $Tm_P$  is the most meaningful physiologic measurement of renal tubular activity in any consideration of phosphate excretion Other appraisals of the renal mechanism for excretion of phosphate have frequently been used Among these are the renal clearance of phosphate ( $C_{Po}$  = excreted phosphate/serum phosphorus) the percentage of filtered phosphate that is reabsorbed ( $\%TRP$ ) and the fraction of filtered phosphate that is not reabsorbed ( $= C_{Po}/C_I$ ) These estimations are made without loading the excretory mechanism with phosphate Since these three calculations are all influenced by the serum phosphate concentration as well as by glomerular and tubular function direct interpretation of

on tubular reabsorption of phosphate are needed. The evidence presented to date is that parathyroid hormone (which has many actions similar to those of the vitamin D group of sterols), cortisone, possibly stilbestrol, and possibly vitamin D under certain circumstances (see below) all decrease the tubular reabsorption of phosphate. This suggests a common mechanism of action on the renal tubules. The possibility that abnormal steroids may be involved in vitamin D-resistant rickets is discussed further on under Possible Mechanisms of Pathogenesis. Other relationships between cortisone and vitamin D are discussed under Other Possible Mechanisms of Pathogenesis.

### *Chemical Substances Possibly Competing for Tubular Reabsorption of Phosphate*

A number of substances appear to compete with inorganic phosphate for renal tubular reabsorption. Thus, when the filtered load of any of these is increased and its rate of tubular reabsorption increases, the tubular maximum for reabsorption of phosphate is simultaneously depressed. Glucose [72-73], acetoacetate [74], bicarbonate [75], glycine, and alanine [52] are known to have this effect. It seems probable that glucose and acetoacetate affect phosphate reabsorption through a mechanism different from that of amino acids and bicarbonate. No direct studies of the simultaneous effects of these agents have been made. Chlorzine, in doses which inhibit or block tubular reabsorption of glucose, increases the tubular reabsorption of phosphate. This suggests that even the normal rate of reabsorption of glucose has a slightly suppressive effect on phosphate reabsorption [72-73]. The carbonic anhydrase inhibitor acetazolamide depresses the  $Tm_p$  concomitant with increasing bicarbonate excretion [75-76].

The interrelationships between the pathways for tubular reabsorption of these substances are quite complex and in need of much further study. Lotpeich discusses this problem in relation to the hypothetical biochemical pathway which actively transfers phosphate across the tubular cell membrane [76a]. The inference that the inhibition may be of a competitive type is pertinent to the decreased tubular reabsorption of phosphate in vitamin D-resistant rickets. The occasional appearance of slight glucosuria and aminoaciduria in this disorder is compatible with possible abnormalities in the metabolism of these agents in the production of the phosphaturia. These interrelationships are discussed in more detail in Chap. 37.

There is equivocal evidence concerning the effects of hypokalemia on the tubular reabsorption of phosphate. Hogben and Bollman [32] found that potassium infusion produced a rise in  $Tm_p$ , but the effect was inconsistent. In one patient with potassium deficiency and disease, Mahler and Stranbury [77] found increased excretion of phosphate despite a low

doubt that one specific action of the parathyroid hormone is on renal tubular reabsorption of phosphate. Earlier studies of this action are referred to by Bartter [44] and Lotspeich [56].

The effects of varying intakes of calcium and phosphate on renal tubular reabsorption of phosphate are probably mediated through the parathyroid glands. Prolonged increased intake of phosphate results in a reduction in the amount of phosphate reabsorbed by the renal tubule [57]. Prolonged elevation of serum phosphorus level by repeated infusions leads to a marked fall in  $Tm_p$  in normal persons but probably not in hypoparathyroid patients [58]. A low intake of calcium produces parathyroid hyperplasia in animals [59-60]. Secondary hyperplasia of the parathyroid glands in patients with renal disease is associated either with decreased total calcium concentration in the serum [61] (and decreased ionized calcium of the serum [62]) or with elevated serum phosphorus concentration or both. Calcium infusion is usually followed by a temporary increase in tubular reabsorption of phosphate (unloaded) and in  $Tm_p$  [63-66]. All these findings are best interpreted as indicating that a low calcium intake or absorption or a high phosphorus intake leads to parathyroid hyperplasia which in turn leads to decreased tubular reabsorption of phosphate.

There is evidence that in the chicken parathyroid hormone increases the net tubular secretion of phosphate [41]. Since tubular secretion of phosphate in man has not been excluded the possibility must be kept in mind that parathyroid hormone also affects tubular secretion in man.

Certain other hormones or related compounds have been studied for their effects on renal phosphate excretion. Cortisone given intravenously to dogs produces an immediate fall in  $Tm_p$  but deoxycorticosterone does not [67-68]. The evidence is less clear cut in man. ACTH and cortisone given in large amounts for several days cause increased phosphate excretion because of a decrease in the net amount of phosphate reabsorbed [40]. In one experiment the evidence suggested net tubular secretion. In acute studies using intravenous hydrocortisone no change in  $Tm_p$  in some normal subjects and a slightly decreased  $Tm_p$  in others was found [69]. A decrease was more frequent when  $Tm_p$  was expressed per unit volume of glomerular filtrate [69]. Diethylstilbestrol given for 14 to 21 days to five patients (three with osteoporosis) was followed by some decrease in  $Tm_p$  in each [70]. One cannot say from these data whether stilbestrol has a direct action on the renal tubules.

Triiodothyronine given intravenously to dogs in 1 mg doses induced increased renal excretion of phosphate and it was stated that tubular reabsorption was decreased [71]. However serum phosphorus level and glomerular filtration rate rose and in the published data the calculated rate of tubular reabsorption actually increased.

Further studies of the action of these hormones and related compounds

compared with the  $Tm_p$  of a previous day. The data are included in Table 36-4. Glomerular filtration rate did not change. Huge doses of vitamin D given to normal dogs (1.25 to 3 mg per kg given over 5 days) depress glomerular filtration rate as well as  $Tm_p$ , but the fall in  $Tm_p$  is out of proportion to the decline in glomerular filtration rate [88].

These results may represent an action of massive doses of vitamin D and related compounds which is shared with other sterols and which is different from the physiologic effects of vitamin D on the kidney.

Vitamin D in large doses raises the serum concentration and excretion of citrate to abnormally high levels [89-90]. Since infusing citrate into a hypoparathyroid subject does not produce increased phosphate excretion [80] whereas vitamin D has this effect in the same type of subject [84-86], it seems unlikely that vitamin D affects phosphate excretion through its effect on citrate metabolism. More definitive studies of this point are needed.

#### THE RENAL ABNORMALITY IN PHOSPHATE EXCRETION

Beginning with the observations of Robertson Harris and McCune [2] in 1942 many studies of patients with vitamin D resistant rickets

Fig. 36-5 Values for maximal tubular reabsorption of phosphate ( $Tm_p$   $\mu$  moles per 100 ml glomerular filtrate) on 10 members of the Hurler kindred of Winters et al. ■ = male, ● = female. The mean and two standard deviations (—) for the values of  $Tm_p$  of 14 normal subjects [3, 5, 45 and unpublished observations of the authors] are represented by the lines.

have shown abnormally high rates of excretion of phosphate or clearances of phosphate, especially when considered with respect to their low values of serum phosphorus [3, 5, 17, 21, 23, 29, 37, 91-93]. This has been true both in cases with a clear-cut familial incidence [3, 23, 29, 37] and in other cases lacking an obvious family history.

Unequivocal demonstration of the nature of the principal renal abnormality in this disease though not of its mechanism has come from

serum phosphorus level when the patient was hypokalemic. Phosphate excretion and serum phosphorus level returned to normal when the potassium deficiency was corrected but other changes were going on simultaneously, such as the correction of a metabolic acidosis. As noted above, deoxycorticosterone had no effect on  $Tm_p$  in an experiment in which serum potassium concentration fell from 3.8 to 2.6 mEq per l [67].

Systemic acidosis is accompanied by decreased tubular reabsorption of phosphate in the nonloaded state in the human being [78], in the dog conflicting evidence has been presented [72-79].  $Tm_p$  is not affected by acidosis in either species.

Nordin and Fraser [80] found that infusion of sodium citrate led to increased phosphate excretion without significant change in serum phosphate concentration. Glomerular filtration rate was not measured but if it did not change, then tubular reabsorption of phosphate was diminished. This response did not occur in one hypoparathyroid subject and Nordin and Fraser suggested that the effect of citrate was mediated through the parathyroid gland, i.e., that the infused citrate formed a complex with the ionized calcium of serum, thereby lowering ionized calcium and stimulating parathyroid hormone secretion. The rate of citrate excretion was not measured. The direct role of citrate excretion if any, in phosphate excretion has not been evaluated.

#### *Action of Vitamin D on Renal Tubular Function and Excretion of Phosphate*

Existing information does not permit an unequivocal statement concerning the effects of vitamin D on renal tubular function in normal or diseased states.

Vitamin D given to vitamin D-deficient rachitic patients and dogs produces an increased tubular reabsorption of phosphate [81] and increased  $Tm_p$  [82, 83]. This result could be a direct effect of vitamin D on the renal tubule. It might also be an indirect effect, with the well established action of vitamin D in increasing calcium absorption resulting in suppression of parathyroid function. As Albright has pointed out [81] these two possibilities could be differentiated by repeating the study on rachitic dogs with and without parathyroidectomy, but this has not yet been done.

In hypoparathyroid human subjects vitamin D in massive doses (equivalent to 5 to 10 mg calciferol a day—1 000 times the maintenance requirement of vitamin D) and dihydrotachysterol (A.T. 10) 6 to 12 mg per day have both produced significant increases in phosphate excretion concomitant with a falling serum phosphorus [84-86]. Unless glomerular filtration rate changed these results indicate decreased tubular reabsorption of phosphate.

Rupp and Swoboda [87] gave 20 mg of a vitamin D<sub>2</sub>-hydroxol intravenously to one normal subject and found a slightly lower  $Tm_p$  when

| Subject's name | Sex | Height<br>in | Values before phosphate load |            |                                       | Values after phosphate load | Rate of phosphate excretion<br>$\mu\text{M}/100\text{ ml GF}$ |
|----------------|-----|--------------|------------------------------|------------|---------------------------------------|-----------------------------|---|
|                |     |              | Protein                      | Creatinine | Excretion<br>$\mu\text{M}/\text{min}$ |                             |   |
|                |     |              |                              |            |                                       |                             |   |

## A Hypophosphatemic patients with deformities

|       |    |   |    |      |      |     |      |      |     |     |
|-------|----|---|----|------|------|-----|------|------|-----|-----|
| V 1   | 41 | M | 65 | 1.8  | 0.41 | 144 | 13.8 | 31.6 | 135 | 0.7 |
| V 11  |    |   |    | 1.36 | 0.63 | 131 | 18.5 | 60.3 | 170 | 0.1 |

## C Normal healthy subjects

|     |    |   |    |      |      |  |  |  |      |      |
|-----|----|---|----|------|------|--|--|--|------|------|
| V 8 |    | F | 68 | 3.00 | 0.41 |  |  |  | 1.3  | 1.01 |
| V 5 | 31 | M | 71 | 3.54 | 1.14 |  |  |  | 1.41 | 1.31 |

Column headings:  $V$  = serum concentration of inorganic phosphorus;  $C_r$  = clearance of inulin;  $L$  or  $I$  = rate of phosphate excretion;  $H$  = rate of phosphate reabsorption;  $GFR$  = glomerular filtrate.

† After vitamin D 300,000 IU/day for 6 months.

‡ After low-calcium diet plus Basaljel 180 ml/day for 7 days.

§ Normal diet intravenous loading with calcium gluconate (13 mg calcium per kg over 6 hr). Value of rephosphate loading were obtained at 4 to 5 hr after phosphate loading at 5 to 6 hr after start of calcium infusion.

Source: H. W. Winters et al. [5] and previously unpublished observations of the authors.

TABLE 36-2 SUMMARY OF EVIDENCE ON PHOSPHATE EXCRETION IN PATIENTS WITH VITAMIN D-DEFICIENT RICKETS RECALCULATED

| Adult and/or Child (yr) | Age at onset (yr) | Sex | GFR ml/min          | Urine P (mg/100 ml) | Cr (mg/dl) | Cr (ml/min) | % absorbed (calculated from P balance) | % absorbed (calculated from P balance) | Final P (mg/100 ml) |
|-------------------------|-------------------|-----|---------------------|---------------------|------------|-------------|--|--|---------------------|
| Adult (19)              | 18                | F   | Blood 100 mg/100 ml |                     |            |             |  |  |                     |
| Child (19)              | 13                | F   | NPN 26 mg/100 ml    |                     |            |             |  |  |                     |

arginine [97] or methionine [99] are probably abnormal in patients with vitamin D-resistant rickets but more specific information is needed on the disease of the subjects and on comparable results in normal persons.

There is meager evidence for an association of renal glycosuria with vitamin D-resistant rickets. The only patients described so far with this combination and with family histories of vitamin D-resistant rickets are the young boy reported by Fanconi and Girardet [17] and Tobler et al [29] who was unusual in several other ways and one of two brothers both of whom were found by Dent [91] to have vitamin D-resistant rickets. Only rare instances of glycosuria have been reported among nonfamilial cases [100-101]. The large body of negative evidence for renal glycosuria in patients with familial hypophosphatemia and vitamin D-resistant rickets suggests that an abnormality in glucose reabsorption does not participate in the production of the increased phosphate excretion. Quantitative determinations of tubular maxima for glucose reabsorption in subjects with clear family histories are needed to clarify this point.

The glomerular filtration rate has been normal in the patients in whom it has been measured (Tables 36-2, 36-3). Freeman and Dunskey [100] also found a normal exogenous creatinine clearance in their patient. Acidification of the urine is probably normal as shown by normal  $\text{CO}_2$  content of the blood. The only exceptions have been isolated low values for  $\text{CO}_2$  content in the child reported by Fanconi and Girardet [17] and in one patient reported by Snoboda [28]. In addition a few observers have found a normal response to an ammonium chloride load [21, 94, 102]. Concentrating ability is normal as are concentration and dilution tests [17, 21]. There is no evidence of abnormalities in sodium or potassium excretion and serum concentrations are normal. Renal response to administration of parathyroid hormone is probably normal (see below). Response to other agents like cortisone has not been determined. There are no reports of more quantitative measures of renal function such as the tubular maxima for excretion of para aminohippurate.

The renal abnormality in familial hypophosphatemia thus appears to involve solely the tubular reabsorption of phosphate. More quantitative information is needed in certain areas: in particular the response of subjects with clearly defined genetic backgrounds to loading with amino acids, glucose and para aminohippurate. An equally great need is for histologic and histochemical study of renal tissue. Such information is entirely lacking.

#### EFFECTS OF VITAMIN D ON RENAL FUNCTION IN VITAMIN D-RESISTANT RICKETS

The renal effects of vitamin D in this disorder have been incompletely studied. The administration of large doses of vitamin D causes either no

measurement of  $Tm_F$  by Rupp and Swoboda [87] and by Winters et al [7, 8]. In both studies the  $Tm_F$  was distinctly low. Tables 36.2 and 36.3 and Fig. 36.5 present the available data. The values for  $Tm_F$  in members of the "C" kindred of Winters et al. were about equally low in four adults with hypophosphatemia without bone disease and in four adults with hypophosphatemia and bone disease.

The hypophosphatemia appears to be almost entirely due to decreased tubular reabsorption of phosphate. Phosphate balance may be otherwise normal (see below). At sufficiently low serum phosphate levels such as when intake is very low, phosphate balance is maintained with minimal phosphate excretion [94].

The possibility that extrarenal factors such as parathyroid hormone are involved in the pathogenesis of the decreased renal tubular reabsorption of phosphate is discussed below, under Possible Mechanisms of Pathogenesis.

#### OTHER RENAL ABNORMALITIES

Except for the low tubular reabsorption of phosphate, renal function is normal as far as can be determined from present data. The occurrence of slight degrees of aminoaciduria and glycosuria in a few cases suggests that in some instances of this disease there may be additional defects similar to those in Fanconi syndrome. In attempting to evaluate the degree of association if any between familial hypophosphatemia and the Fanconi syndrome, the study of families with well documented genetic patterns should prove particularly valuable. In one of the families most carefully studied from a genetic viewpoint, total amino acid excretion in five hypophosphatemic persons was normal [8]. Paper chromatograms of the amino acids of the urine of a number of affected adults and children in the families studied by these authors also gave normal results [8a]. All other determinations of aminoaciduria in familial instances of the disorder have been normal [18, 21, 23, 29] except for one case first reported by Fanconi and Girardet [17]. This child had slightly elevated serum amino acid concentration on one occasion and slightly increased urinary excretion of amino acids on three occasions. The patient also had slight glycosuria [29], this coupled with unusual facies and an abnormal skull x-ray led Tobler and coworkers to question whether he had more than simple vitamin D-resistant rickets [29].

Observations on aminoaciduria in patients with vitamin D-resistant rickets without family history have been more varied. Some patients have had no abnormal aminoaciduria [25, 29, 96]. In others abnormally high excretion of various amino acids has decreased upon administration of large doses of vitamin D [21, 25, 97], a response similar to that of the aminoaciduria of vitamin D-deficiency rickets to smaller doses [97, 98]. The excretory patterns of amino acids after loading with histidine-

excretion of these substances. This response was recorded throughout two to six 6-day collection periods. Since there were no measurements of glomerular filtration rate it is not known whether any change in tubular reabsorption of phosphate occurred. If glomerular filtration rate did not change significantly then tubular reabsorption of phosphate must have decreased. The authors proposed that this indeed did happen and may have been due to stimulation of parathyroid hormone by the fall in serum calcium concentration.

TABLE 36-4 ACUTE EFFECT OF INTRAVENOUS VITAMIN D ON MAXIMAL TUBULAR REABSORPTION OF PHOSPHATE ( $T_{mp}$ )

| Case No | Dose of vitamin D | Range of $T_{mp}$ |                             |                        |
|---------|-------------------|-------------------|-----------------------------|------------------------|
|         |                   | Before vitamin D  | Immediately after vitamin D | 1 week after vitamin D |
| 5 (RR)† | 0 mg              | 97-100            | 91-101                      | 103-119                |
| 5 (RR)  | 10 mg             | 100-145‡          | 144-147                     |                        |
| 3 (RR)  | 10 mg × 2         | 69-84‡            | 110-113                     | 5-8                    |
| Normal  | 10 mg × 2         | 174-208‡          | 143-148                     | 172-175                |

Expressed in micromoles per 100 ml glomerular filtrate

† RR = resistant rickets

‡ The 3 control measurements of  $T_{mp}$  were done on a previous day and do not represent control values immediately prior to injection of vitamin D

§ Not recalculated from Rupp and Swoboda [8]

In summary, large doses of vitamin D may result in increased renal tubular reabsorption of phosphate in patients with familial hypophosphatemia and vitamin D-resistant rickets. Even if true, this is not necessarily a direct action of vitamin D. The proposal originally made by Albright et al [84, 86] and subsequently by numerous students of this disease—that the purported change in tubular reabsorption is the result of diminished parathyroid activity as calcium absorption improves—has yet to be proved or disproved.

## GASTROINTESTINAL ABSORPTION OF CALCIUM AND PHOSPHATE

### NORMAL FEATURES AND THE ROLE OF VITAMIN D

Normal adults and children supplied with physiologic amounts of vitamin D and dietary calcium above a minimal level (0.45 to 1.0 gm per day [107, 108]) absorb enough calcium to remain in calcium balance. Children achieve enough positive balance for normal growth of bone. A deficiency of vitamin D intake uniformly leads to progressively lowered absorption of calcium until fecal excretion of calcium equals intake.

change or a rise in serum phosphorus level accompanied by either no change or a fall in urinary phosphate excretion [1, 2, 17, 94, 102]. Whether these changes are the result of decreased glomerular filtration rate or increased renal tubular reabsorption of phosphate is not known and cannot be determined from measurement of phosphate clearance alone. The studies reported by Robinson and Nelson [103] in which  $C_{Cr}$  remained constant as serum phosphorus concentration rose with vitamin D therapy, offer an illustration of the care with which clearance data must be interpreted. If glomerular filtration rate remained constant as inferred in four of six subjects a constant  $C_{Cr}$  in association with a rising serum phosphorus concentration requires a simultaneous increase in both phosphorus reabsorption and excretion in these subjects. Only if there were a considerable fall in glomerular filtration rate could the results of Robinson and Nelson indicate no change or a decrease in tubular reabsorption of phosphate with vitamin D therapy.

There have been few direct measurements of glomerular filtration rate in relation to vitamin D therapy. In one subject stated to have familial vitamin D-resistant rickets Klein and Gow [104] found a rise in inulin clearance one day after giving 600 000 units (22 mg) of vitamin D intramuscularly. Robinson and Nelson [103] described a fall in glomerular filtration rate in two of six subjects with vitamin D-resistant rickets on prolonged vitamin D therapy. In one subject with this disease reported by Dent and Harris [5] daily creatinine excretion did not change during vitamin D administration.

Rupp and Swoboda [87] have reported the acute response of phosphate excretion to intravenous vitamin D administration both in nonloaded and phosphate-loaded patients. They studied three children with familial vitamin D-resistant rickets. Glomerular filtration rate was little affected. The effects on  $Tm_p$  are summarized in Table 36-4. In two patients  $Tm_p$  was higher immediately after administration of vitamin D and in one it did not change. There was no change in phosphate reabsorption in one subject studied without phosphate loading. These data cannot be considered conclusive evidence for a direct effect of vitamin D on phosphate reabsorption.

Measurements of  $Tm_p$  and phosphate reabsorption in the nonloaded state 1 week after these acute intravenous doses were given were not different from control observations [87]. If vitamin D has an effect on renal function it is short lived. In a preliminary report Dent has stated that there is a rise in  $Tm_p$  with administration of vitamin D [105]. The route, amount and duration were not specified.

Zetterstrom et al [106] made the curious and thus far unique observation in two children with vitamin D-resistant rickets that the initial response to 100 000 to 200 000 I U per day orally was a fall in serum concentrations of phosphate and calcium without change in absorption or

in vitamin D-resistant rickets is furnished by the studies of Saville et al [114] and Fraser et al [119]. These workers found that administration of large amounts of phosphate either orally or intravenously without large doses of vitamin D will induce increased positive balances of calcium and phosphorus and initiate healing of the rickets. Studies of the absorption of calcium and phosphate in affected members of families with the best worked out pedigrees based on hypophosphatemia have not been made.

In summary the gastrointestinal absorption of calcium and secondarily of phosphate is probably abnormally low. This is particularly evident in children with active rickets who do not have a sufficiently positive balance for normal growth. In affected family members with asymptomatic hypophosphatemia impairment in calcium and phosphate absorption may not be apparent. Bony development is normal both clinically and radiologically. Vitamin D in massive doses will induce increased absorption of calcium and phosphorus. This is probably no different from what occurs in normal persons despite the lack of response to physiologic amounts of vitamin D. Large increases in intake of phosphate also produce increased absorption of phosphate and probably of calcium.

### ABNORMALITIES IN METABOLISM OF BONE

A thorough discussion of the normal mechanism of formation of bone and the pathogenesis of rickets due to deficiency of vitamin D is beyond the scope of this chapter; good descriptions may be found in Eliot and Park [120], Neuman and Neuman [121] and Bourne [122].

In considering the bony abnormalities found in familial hypophosphatemia and vitamin D-resistant rickets it must be remembered that this inherited disorder can be manifested by hypophosphatemia and diminished tubular reabsorption of phosphate alone with *no apparent bone disease*. Although no bone tissue has been examined histologically from such subjects there are no radiologic abnormalities. The only clinically discernible abnormality is slightly shorter stature than that of normophosphatemic siblings [8]. This virtual lack of bone disease despite hypophosphatemia indicates (1) that the genetically transmitted abnormality is not concerned directly with bone metabolism and (2) that factors other than simple hypophosphatemia are participating in the disease in patients who develop bone disease.

Two different types of bony abnormalities have been described in patients with vitamin D-resistant rickets. The most characteristic finding and the one which gives the disease its name is the typically rachitic appearance of the epiphyseal region. There is a markedly expanded zone of proliferating cartilage with increased osteoid tissue and invasion by wide tortuous blood vessels [1, 16, 28, 94, 123, 124]. The e

Urinary calcium excretion may become virtually zero. Studies of animals and man on calcium free diets show that little if any of the fecal calcium is due to calcium excretion into the gastrointestinal tract [84, 86, 110, 111]. The administration of vitamin D to vitamin D-deficient subjects leads to an increase in calcium absorption [111-113]. This action of vitamin D is the most clearly established role of the vitamin in maintaining normal metabolism of calcium and phosphate. The mechanism of action has not been determined.

Intestinal absorption of phosphate is probably not directly dependent upon vitamin D [110]. In vitamin D-deficient animals or man receiving calcium the phosphate absorption is low. This is thought to be secondary to poor absorption of calcium and the consequent sequestration of calcium phosphate within the intestine [84, 110].

#### ABNORMALITIES IN ABSORPTION OF CALCIUM AND PHOSPHORUS IN FAMILIAL HYPOPHOSPHATEMIA AND VITAMIN D-RESISTANT RICKETS

Children with vitamin D-resistant rickets before treatment with massive doses of vitamin D excrete virtually all their ingested calcium in the feces. Urinary calcium excretion is low. These subjects have slightly positive or slightly negative balances for calcium but they clearly lack the positive balance which is characteristic of the normal growing child. Total phosphate balance is comparable to the calcium balance but a larger proportion of the ingested phosphate is absorbed and excreted in the urine. The findings are similar in the few studies of patients with vitamin D-resistant rickets with [3, 5, 17, 114] and without family histories [1, 94, 115, 116].

In vitamin D-resistant rickets large doses of vitamin D (2.5 to 37.5 mg per day) uniformly increase the absorption of calcium while urinary excretion remains low. Simultaneously the phosphate balance becomes positive primarily because of increased absorption. This response to very large doses of vitamin D is similar to the response of patients with vitamin D-deficiency rickets to smaller doses. Dihydrotachysterol (A.T. 10) in doses in the same range as those of vitamin D (1.25 to 12.5 mg per day) produces similar changes in calcium absorption in vitamin D-resistant rickets [86, 114, 117].

The response of patients with resistant rickets to massive doses of vitamin D is similar to that of other subjects. Albright and his coworkers [84-86] for example found comparable increases in calcium absorption in patients with primary hypoparathyroidism and patients with idiopathic hypercalcaemia given large doses of vitamin D or dihydrotachysterol. Normal man and normal rats also have increased calcium absorption when given large doses of vitamin D [111, 118].

Further evidence that poor absorption of calcium is not the only defect

in some areas. Toxic doses of vitamin D clearly produce abnormal amounts of bone resorption [111]. Bauer et al [11] in studies in man found that the estimated increase in total daily accretion of phosphate salt into bone due to vitamin D was two to six times the extra retention of phosphate from the gastrointestinal tract promoted by vitamin D. The changes were of similar magnitude in two subjects with vitamin D-deficiency rickets treated with 30 000 to 45 000 I U per day and in two subjects with vitamin D-resistant rickets treated with 150 000 to 500 000 I U per day. Thus it appears that under the influence of vitamin D calcium and phosphate are mobilized from one part of bone to be deposited in another.

As Nicolaysen and Feg Iarsen have pointed out [111] it is both important and difficult in attempting to establish the actions of vitamin D to distinguish between effects of vitamin D on calcium absorption and direct effects on bone. The same problem exists in the study of the pathologic physiology of vitamin D-resistant rickets. One cannot say from available evidence whether the response of the bone to normal levels of vitamin D would be normal if the serum concentrations of calcium and phosphate were maintained at normal levels for prolonged periods by means other than very large doses of vitamin D.

The similarity of the changes in metaphysis and diaphysis to those seen in osteochondrodystrophy raises the possibility that this bony abnormality is another congenital presumably inherited defect in these patients and not directly related to hypophosphatemia or to vitamin D. The lesion could also be a direct effect of parathyroid overactivity although the changes described have not been entirely typical.

### POSSIBLE MECHANISMS OF PATHOGENESIS AND QUESTIONS STILL UNANSWERED

This discussion of pathogenesis of familial hypophosphatemia and vitamin D-resistant rickets will be focused on the two abnormalities which the authors consider to be the most characteristic features of the disorder: hypophosphatemia and decreased renal tubular reabsorption of phosphate. The other abnormalities thus far identified—low gastrointestinal absorption of calcium and the bony abnormalities—will be discussed in so far as they bear upon the pathogenetic possibilities to be presented. A final decision about mechanism cannot now be made.

#### *A Genetically Determined Intrinsic Renal Tubular Defect in Reabsorption of Phosphate*

This possibility offers the simplest explanation for the occurrence of hypophosphatemia and decreased renal tubular reabsorption of phosphate. Consistent with this hypothesis are the facts that hypopho-

changes are present in cases with and without family histories. The radiologic changes in the epiphyseal area are entirely characteristic of vitamin D-deficiency rickets.

A second type of abnormality has been found in the compact bone of the metaphyses of long bones. In biopsies from such areas in two cases Engfeldt et al. [16] observed an abnormal, irregular mosaic formation of the Haversian system and trabeculae, very little osteoid and probably an increase in osteoblastic borders and "resorption cavities." Others have described similar changes [3, 29]. These abnormalities may be present before treatment with massive doses of vitamin D as well as afterwards [16]. The histologic pattern has some features suggestive of Paget's disease or of experimental hyperparathyroidism [125]. These changes are not always present. In some patients bone from metaphysis has been almost normal [17, 29].

The epiphyseal lesion typical of rickets heals in most instances when the patients are treated with massive doses of vitamin D. However the healing of the epiphyseal lesion is apparently not dependent upon an action of vitamin D on the bone itself but rather upon its action in promoting absorption of calcium and phosphate. Healing can be initiated by supplying large amounts of phosphate intravenously or orally [119] and is accelerated by immobilization of patients at the time of osteotomy without large doses of the vitamin [21, 26, 29, 102]. Vitamin D-resistant rickets and vitamin D-deficiency rickets are alike in not requiring vitamin D for the healing of the epiphyseal lesion. Healing is also initiated in vitamin D-deficiency rickets by supplying large amounts of phosphate intravenously [119] or citric acid-sodium citrate orally [126-128]. An unexplained observation which may be a valuable clue to the difference between vitamin D-deficiency rickets and vitamin D-resistant rickets is that the latter does not heal with administration of citric acid-sodium citrate [12, 23, 102, 120, 129]. Further study of this difference in response to citrate is needed.

The second type of abnormality of bone structure in vitamin D-resistant rickets is more difficult to interpret. This distortion of trabecular structure may simply be another manifestation of rickets slow to develop and slow to heal and accordingly more evident in vitamin D-resistant rickets than in vitamin D-deficiency rickets. In rats [111, 130] and dogs [131] an abnormal trabecular appearance and increase in noncalcium content of the shaft of long bones is a distinctive feature of vitamin D deficiency and is not directly related to absorption of calcium and phosphate. This has suggested to Nicolaysen and coworkers [111, 130] and to Mellanby [131] that vitamin D has a direct function in normal bone formation. Furthermore Carlsson [132] and Nicolaysen and Eeg Larsen [133] have presented evidence in vitamin D-deficient rats which suggests that vitamin D in physiologic doses causes increased bone resorption.

in some areas. Toxic doses of vitamin D clearly produce abnormal amounts of bone resorption [111]. Bauer et al [11] in studies in man found that the estimated increase in total daily accretion of phosphate salt into bone due to vitamin D was two to six times the extra retention of phosphate from the gastrointestinal tract promoted by vitamin D. The changes were of similar magnitude in two subjects with vitamin D-deficiency rickets treated with 30 000 to 40 000 I U per day and in two subjects with vitamin D-resistant rickets treated with 150 000 to 500 000 I U per day. Thus it appears that under the influence of vitamin D calcium and phosphate are mobilized from one part of bone to be deposited in another.

As Nicolay en and Leg Larsen have pointed out [111] it is both important and difficult in attempting to establish the actions of vitamin D to distinguish between effects of vitamin D on calcium absorption and direct effects on bone. The same problem exists in the study of the pathologic physiology of vitamin D-resistant rickets. One cannot say from available evidence whether the response of the bone to normal levels of vitamin D would be normal if the serum concentrations of calcium and phosphate were maintained at normal levels for prolonged periods by means other than very large doses of vitamin D.

The similarity of the changes in metaphysis and diaphysis to those seen in osteochondrodystrophy raises the possibility that this bony abnormality is another congenital presumably inherited defect in these patients and not directly related to hypophosphatemia or to vitamin D. The lesion could also be a direct effect of parathyroid overactivity although the changes described have not been entirely typical.

### POSSIBLE MECHANISMS OF PATHOGENESIS AND QUESTIONS STILL UNANSWERED

This discussion of pathogenesis of familial hypophosphatemia and vitamin D-resistant rickets will be focused on the two abnormalities which the authors consider to be the most characteristic features of the disorder: hypophosphatemia and decreased renal tubular reabsorption of phosphate. The other abnormalities thus far identified—low gastrointestinal absorption of calcium and the bony abnormalities—will be discussed in so far as they bear upon the pathogenetic possibilities to be presented. A final decision about mechanism cannot now be made.

#### *A Genetically Determined Intrinsic Renal Tubular Defect in Reabsorption of Phosphate*

This possibility offers the simplest explanation for the occurrence of hypophosphatemia and decreased renal tubular reabsorption of phosphate. Consistent with this hypothesis are the facts that hypophos-

phosphatemia has a simple genetic pattern, and that there is decreased tubular reabsorption of phosphate in all instances in which it has been looked for. One may propose therefore an isolated defect in the tubular mechanism responsible for the transport of phosphate. This explanation originally suggested by Robertson, Harris and McCune [2] has also been offered by Dent, Fanconi and others [17, 27, 91, 134-136].

Certain qualifications must be made for such a proposed intrinsic tubular defect. First, reabsorption of phosphate is only *decreased*, not absent. As the data of Tables 36-2 and 36-3 show, these patients do have a significant rate of reabsorption of phosphate which is about half of normal. It is possible that there may be two "sites" or mechanisms by which phosphate is reabsorbed, only one of which is absent or blocked in familial hypophosphatemia.

A second qualification is that the tubular phosphate-reabsorbing mechanism which is still intact in these patients is probably responsive to parathyroid hormone. This is discussed below in the next section.

The response of the phosphate reabsorptive mechanism in subjects with vitamin D-resistant rickets to other agents which diminish tubular reabsorption of phosphate has not been studied. It is of interest that all agents whose effect on  $Tm_p$  has been quantitatively determined (parathyroid hormone, cortisone, glucose, acetoacetate, bicarbonate) lower the  $Tm_p$  to approximately the range seen in familial hypophosphatemia. Table 36-5 summarizes the available data. It is possible that all these agents affect (perhaps indirectly) one pathway for phosphate transport, while a second mechanism is independent of their effects. This possibility might be studied by determining the effects of combinations of the agents on  $Tm_p$  in normal and in affected persons.

Some features of this disease are not readily explicable by a simple renal tubular defect, viz. the decreased gastrointestinal absorption of calcium (and phosphate) and the metaphyseal and diaphyseal abnormalities in the bone. It is possible that a (partial) defect in intestinal absorption of phosphate, analogous to the renal tubular defect, could be present. However, the patient of Albright et al. [1] absorbed over 80 per cent of ingested phosphate when on a low calcium intake. Gunther et al. [110] in one patient with vitamin D-resistant rickets found all but 5 per cent of ingested radiophosphorus absorbed when it was not given with food. Similar measurements have not been reported in familial cases.

Fanconi [135] has proposed a sequence of events as follows: the decreased tubular reabsorption of phosphate is the primary determinant of the low serum phosphorus concentration. Accordingly, deposition of bone salts in osteoid tissue is subnormal. Calcium absorption is in some way related to the rate of deposition of calcium in bone and is thus also low. Consistent with this proposal is the fact that healing of the bone disease and increased calcium absorption are initiated by large in-

travenous or oral loads of phosphate [119]. The last link in the above sequence, the dependence of calcium absorption upon rate of bone deposition has not been established.

### *Hyperparathyroidism Secondary to a Defect in Gastrointestinal Absorption of Calcium*

On the basis of their studies on the first patient in whom the diagnosis of vitamin D-resistant rickets was made Albright et al [184] proposed that the primary event is decreased absorption of calcium because of resistance to vitamin D. This leads to a low serum calcium concentration which in turn stimulates parathyroid secretion. Increased parathyroid hormone activity decreases tubular reabsorption of phosphate and hypophosphatemia occurs. Secondary to the hypophosphatemia (as Albright proposed) or due to another direct action of parathyroid hormone on bone (as subsequent work has shown [137-139]) resorption of calcium from bone occurs and raises the serum calcium concentration. If the compensatory overactivity of the parathyroid glands should be just sufficient the final results of this sequence could be normal serum

phthemia has a simple genetic pattern and that there is decreased tubular reabsorption of phosphate in all instances in which it has been looked for. One may propose therefore an isolated defect in the tubular mechanism responsible for the transport of phosphate. This explanation originally suggested by Robertson, Harris and McCune [2] has also been offered by Dent, Lanconi and others [17, 27, 91, 134-138].

Certain qualifications must be made for such a proposed intrinsic tubular defect. First, reabsorption of phosphate is only *decreased* not absent. As the data of Tables 36-2 and 36-3 show, these patients do have a significant rate of reabsorption of phosphate which is about half of normal. It is possible that there may be two "sites" or mechanisms by which phosphate is reabsorbed, only one of which is absent or blocked in *familial hypophosphatemia*.

A second qualification is that the tubular phosphate reabsorbing mechanism which is still intact in these patients is probably responsive to parathyroid hormone. This is discussed below, in the next section.

The response of the phosphate reabsorptive mechanism in subjects with vitamin D-resistant rickets to other agents which diminish tubular reabsorption of phosphate has not been studied. It is of interest that all agents whose effect on  $Tm_p$  has been quantitatively determined (parathyroid hormone, cortisone, glucose, acetoacetate, bicarbonate) lower the  $Tm_p$  to approximately the range seen in *familial hypophosphatemia*. Table 36-5 summarizes the available data. It is possible that all these agents affect (perhaps indirectly) one pathway for phosphate transport while a second mechanism is independent of their effects. This possibility might be studied by determining the effects of combinations of these agents on  $Tm_p$  in normal and in affected persons.

Some features of this disease are not readily explicable by a simple renal tubular defect, viz., the decreased gastrointestinal absorption of calcium (and phosphate) and the metaphyseal and diaphyseal abnormalities in the bone. It is possible that a (partial) defect in intestinal absorption of phosphate analogous to the renal tubular defect could be present. However, the patient of Albright et al. [1] absorbed over 80 per cent of ingested phosphate when on a low calcium intake. Gunther et al. [115] in one patient with vitamin D-resistant rickets found all but 5 per cent of ingested radiophosphorus absorbed when it was not given with food. Similar measurements have not been reported in familial cases.

Lanconi [180] has proposed a sequence of events as follows: the decreased tubular reabsorption of phosphate is the primary determinant of the low serum phosphorus concentration. Accordingly, deposition of bone salts in osteoid tissue is subnormal. Calcium absorption is in some way related to the rate of deposition of calcium in bone and is thus also low. Consistent with this proposal is the fact that healing of the bone disease and increased calcium absorption are initiated by large in-

Lamy et al [21] in one child with nonfamilial vitamin D-resistant rickets or a variant of the Lianconi syndrome found that near the end of a 3 hr calcium infusion the urine became phosphate free (and aminoaciduria previously present also disappeared). Fraser et al have made similar observations on phosphate excretion with more prolonged calcium infusions in two children with vitamin D-resistant rickets: subcutaneous administration of parathyroid extract then restored the phosphaturia [144, 145]. Field and Reiss [146] found that the %TRP rose from low to normal levels in 12 affected members of three families with this disorder. However, since serum phosphorus concentration also remained below normal in these studies, the amount of phosphorus actually being reabsorbed by the tubules remained low. Only by raising serum phosphorus to normal or preferably to a level which clearly saturates tubular reabsorptive capacity, at the time of a calcium infusion, could one hope to differentiate unequivocally between the role of the parathyroid glands and that of an underlying tubular defect. In one such study in an affected adult member (IV-5) of the C kindred of Winters et al [8]  $Tm_p$  in the sixth hour of calcium infusion (13 mg per kg over 6 hr) was low and not significantly different from two previous measurements of  $Tm_p$  in the same subject (Table 36-3). Further studies of this type are needed in familial and nonfamilial instances of the disorder; it is entirely possible that more than one mode of pathogenesis exists.

Parathyroid extract given *intravenously* to several patients with this disorder has produced variable increases in phosphate excretion [17, 28, 29]. It is now known, as best demonstrated by Hiatt and Thompson [34], that intravenously administered parathyroid extract increases glomerular filtration rate to such a degree that no interpretation can be made about a change in tubular reabsorption.

The evidence that hyperparathyroidism is *not* a prominent feature of familial hypophosphatemia is inferential. In patients with hypophosphatemia only, it seems improbable that a defect in calcium absorption could be so delicately balanced by parathyroid overactivity that serum calcium concentration would be maintained at a normal level throughout life without any signs of hyperparathyroidism other than increased phosphate excretion. The absence of clinical or radiologic evidence of bone resorption in the asymptomatic patients is additional evidence against the presence of chronic hyperparathyroidism. Histologic examination of specimens of bone would be most helpful.

It is impossible to decide at present whether the hypophosphatemia and decreased renal tubular reabsorption of phosphate are due to an intrinsic renal tubular defect or to hyperparathyroidism secondary to an intestinal defect in absorption of calcium. Several lines of investigation which might help to clarify this question have already been indicated. It is conceivable that parathyroid hormone depresses the reabsorption

calcium (and normal ionized calcium [62]) low serum phosphorus concentration and diminished renal tubular reabsorption of phosphate which are the findings of patients with vitamin D-resistant rickets

If Albright's scheme is correct, one would expect histologic evidence of parathyroid hyperplasia and evidence of bony changes characteristic of hyperparathyroidism. Albright et al [1] actually found hyperplastic changes in one parathyroid gland removed from their patient. Frame and Smith [136] made a similar observation. No parathyroid glands have been examined in patients with familial histories of this disease. As already noted in the section on the bony abnormality, the changes that have occasionally been found in diaphyseal and metaphyseal regions have been interpreted as similar to those of experimental hyperparathyroidism. Furthermore in a number of patients particularly those reported by Holt [19] the lamina dura has been absent. This finding has been observed more commonly in hyperparathyroidism than in any other type of bone disease but it has not been looked for extensively in other types of rickets and osteomalacia. It has been noted in certain cases of osteomalacia due to steatorrhea and to renal tubular acidosis [90].

In the single report of assay of the serum for parathyroid hormone activity in a patient who probably had resistant rickets Highman and Hamilton [140] found a higher than normal value by their calcium mobilization test. Such a test is only a crude measure of a single parathyroid function and one which may not be correlated with the effects on phosphate excretion [141-143].

Renal tubular reabsorption of phosphate in vitamin D-resistant rickets is probably responsive to changes in parathyroid activity. Albright et al [1] found in their patient that administration of parathyroid hormone (500 units a day intramuscularly for 3 days) caused an increase in phosphate excretion. This dose and route in normal man increase phosphate excretion by decreasing tubular reabsorption without any change in glomerular filtration rate [54].

Suppression of parathyroid function has been the interpretation given to the results of intravenous calcium infusions in normal subjects. Phosphate excretion usually falls following the infusion presumably because of suppression of parathyroid function by the elevated serum calcium concentration. In two affected adult members of the "E" kindred of Winters et al [8] intravenous calcium loading caused a 30 to 60 per cent decrease in phosphate excretion which is similar to what occurs in normal persons [63-65-66]. These results suggested that the kidneys of the patients do respond to changes in parathyroid activity however in the presence of their low levels of serum phosphorus it might have been expected that the urine would have become phosphate free if increased parathyroid activity were the only factor affecting phosphate excretion.

Others have observed more striking responses to calcium infusions

to normal when vitamin D is given. Serum citrate concentration rises to supernormal levels when vitamin D intoxication is produced in patients with vitamin D-deficiency rickets and vitamin D-resistant rickets [39 89 90]. The effects of vitamin D on citrate metabolism are apparently not necessarily related to its effects on promoting calcification of osteoid. Cortisol when given to vitamin D-deficient rats prevents the rise in citrate concentration of serum and bone which vitamin D usually produces but does not block the action of vitamin D in raising the serum calcium and phosphate concentrations and healing of the rickets [100]. Conversely when vitamin D-deficiency rickets in rats is healed by giving calcium and phosphate but no vitamin D the citrate content of bone and serum remains low [133]. It would be interesting to know whether the healing of vitamin D-resistant rickets initiated by phosphate administration or immobilization is accompanied by changes in citrate content of bone or serum.

#### *Other Possible Mechanisms of Pathogenesis*

Kodicek [151] in 1956 gave a preliminary report of abnormal  $\Delta^4$  3 ketosteroids in the urines of seven patients with vitamin D-refractory osteomalacia unrelated to vitamin D administration. Cortisone depresses tubular reabsorption of phosphate in the dog and in man under some circumstances and may decrease intestinal absorption of calcium. A related steroid might well have a more marked effect on these functions and be casually related to this disease. The production of such an abnormal steroid could be genetically determined.

It has also been proposed that there is a generalized abnormality in the intermediary metabolism of phosphate perhaps affecting all body cells [8 29 29]. Studies related to this possibility have thus far been applied to erythrocytes only [102-154] where decreased concentrations of organic phosphate compounds have been found in experimental and naturally occurring rickets. It appears likely that this finding is a reflection of a generally low body content of labile phosphorus rather than the result of an abnormality in intermediary metabolism due to lack of vitamin D [155]. Studies of this type have not been made in patients with familial hypophosphatemia and vitamin D-resistant rickets.

An observation which may indicate a more specific abnormality in vitamin D-resistant rickets is that of Rupp [156] that erythrocytes of such a patient incorporate more radioactive phosphorus into creatine phosphate and less into adenosine triphosphate than erythrocytes of normal subjects.

#### *Summary of Possible Mechanisms of Pathogenesis*

The development of the abnormalities in familial hypophosphatemia and vitamin D-resistant rickets is not yet understood. The presence of a simple genetically determined renal tubular defect in reabsorption of

of phosphate of all tubules more or less equally, whereas in familial hypophosphatemia an intrinsic tubular defect might involve some tubules to a greater extent than others. In the latter circumstance an increased "splay" area in the titration curve might be detectable.

#### *An Abnormality in the Absorption of Vitamin D*

There is little direct evidence for an abnormality in the absorption of vitamin D in vitamin D-resistant rickets. The blood level of the vitamin as measured by the bioassay technique of Warkany is normal prior to treatment with massive doses, and markedly elevated afterwards [20, 116, 120]. In addition the bone disease is not prevented or cured by parenterally administered conventional doses of vitamin D [1, 12, 20, 24, 28, 29] nor is ultraviolet light effective in curing rickets of the resistant type [1, 10, 21, 115, 116, 147].

#### *An Abnormality in the Action of Vitamin D*

The fact that large doses of vitamin D will cure the rickets cannot be considered *prima facie* evidence that the cause of the disorder is a resistance to normal amounts of the vitamin. It has already been pointed out that healing of the rachitic bone lesions is initiated by supplying adequate phosphate without additional vitamin D. The action of massive doses of vitamin D (or comparable doses of dihydrotachysterol) on intestinal absorption of calcium is similar to that seen in persons who do not have rickets of either type.

Nevertheless the possibility must be considered that these patients do have a resistance to vitamin D at the level at which it exerts its action in normal individuals. This "resistance" would presumably be inborn in the familial cases and acquired in the sporadic instances. Support for this view comes from the descriptions of patients who have been only partially resistant and are cured by doses of intermediate size [5, 148]. Other patients have developed increasing resistance to vitamin D and have required larger and larger doses [149]. Certain patients have seemed to respond to dihydrotachysterol when they did not respond to vitamin D<sub>2</sub> or D<sub>3</sub> in large doses [147]. These last observations suggest a resistance to specific sterols as has been described for some patients with hypoparathyroidism [149]. No familial case of sterol specific resistance has been described.

Tobler et al. [29] refer to preliminary studies by Flückiger of a serologic reaction to vitamin D, found in the serum of patients with vitamin D-resistant rickets but not in the serum of normal persons. Further evidence on this point is needed.

Clues to the role of vitamin D in familial hypophosphatemia and vitamin D-resistant rickets might come from studies of citrate metabolism. In vitamin D-deficiency states a low content of citrate is found in bone, intestines, kidney, serum and urine. These levels promptly return

hypophosphatemia. A clear generation to generation transmission of the trait emerged and there was no evidence of *skipping*.

The same result was found not only in other portions of this same kindred but also in three additional unrelated kindreds studied subsequently [9]. On the basis of these studies which include a total of 78 hypophosphatemic persons, the following conclusions were drawn:

1. All of the 40 persons who had skeletal disease or deformities were hypophosphatemic.

2. An additional 38 individuals were hypophosphatemic but had no definite evidence past or present of skeletal disease.

Fig 36-6 A portion of the pedigree of the F kindred of Winters et al [9] scored according to the presence of skeletal disease. No clear-cut pattern of inheritance can be identified.

3. In these 38 were included all 11 instances of proved or probable skipping which were scored when skeletal disease was used as the criterion for scoring.

4. Hypophosphatemia was inherited in a clear and simple fashion: each hypophosphatemic person had one hypophosphatemic parent in all of the 50 instances where the requisite data were available.

5. No hypophosphatemic person had more than one hypophosphatemic parent in a number of matings where both parents were examined.

Brothers and sisters of hypophosphatemic persons included both normal and affected persons in approximately equal numbers.

On the basis of these results it is apparent that hypophosphatemia is inherited as a dominant trait with a high degree of penetrance (perhaps not complete penetrance in young girls as indicated below) but the transmission of hypophosphatemia even if fully penetrant is insufficient to produce overt bone disease. There can be little doubt that hypophosphatemia is an important but not the sole determinant of bone disease.

These studies also indicate that the mode of transmission is not autosomal but rather is sex-linked. This conclusion is based upon the authors

phosphate would account very well for the findings in those patients with asymptomatic hypophosphatemia but any attempt to explain the frequent additional findings—the bony abnormalities and defective absorption of calcium—on the basis of a renal tubular defect immediately becomes speculative. The possibility that the primary defect is in absorption of calcium, with an associated secondary hyperparathyroidism has been neither proved nor disproved but seems an unlikely explanation for the existence of asymptomatic hypophosphatemic individuals in the involved families. There is no direct supporting evidence for the proposal that there is an abnormality in the metabolism of vitamin D or a resistance to its action at normal levels. The action of large doses in curing the rachitic lesions can be explained in terms of the action of such doses in normal persons. The evidence for a disturbance in steroid metabolism may be a promising lead.

### GENETIC ASPECTS

There is a definite tendency for vitamin D-resistant rickets to occur in families. In 65 adequately documented cases in the literature prior to 1958 over half had a positive family history [8]. From studies of small pedigrees in which affected individuals were scored on the basis of overt bone disease several workers [9-11] advanced the hypothesis that the disease was transmitted as an autosomal dominant trait. However the overt form of the disease had been reported more frequently in females than in males. Analysis of the distribution of normal and affected females and males among the progeny of affected persons in the earlier studies revealed a deviation from the 1:1:1:1 ratio predicted by the autosomal dominant hypothesis. The primary cause of this deviation was an excess of affected females [8]. These considerations suggested either that there is a strong influence of sex on the expression of an autosomal trait or that some other mode of transmission is operative.

Winters et al. [8] reinvestigated the genetic aspects of the disease in a large North Carolina kindred (E kindred). Individuals were scored not only on the basis of skeletal disease but also on the basis of the level of serum inorganic phosphorus (see Hypophosphatemia and the Abnormality in Renal Excretion of Phosphate). Comparison of these two methods of scoring revealed that the latter is a superior discriminant for the trait. This point is illustrated in Figs. 36-6 and 36-7 where a portion of the E kindred is reproduced. In Fig. 36-6 individuals were scored as affected on the basis of clinical, radiographic or historical evidence of active rickets (children) or postrachitic deformities (adults). Using this method there was no clear cut pattern of inheritance and several instances of skipping of a generation were noted. This may be contrasted with the findings in Fig. 36-7 where scoring was based upon

own studies of four kindreds. In the *classified* progeny of affected fathers all 16 males were normal while all 20 of the females were affected (Table 36-6). The chance of this distribution occurring on the basis of an autosomal dominant mechanism is virtually nil.

A sex-linked dominant mechanism implies that the abnormal gene resides on the X-chromosome. An affected female is therefore heterozygous ( $X^*X$ ) whereas an affected male lacking the normal allele is hemizygous ( $X^*Y$ ). Since the male progeny of an affected male receive their Y-chromosome from their fathers they would all be normal. On the other hand female progeny of an affected male receive the single  $X^*$  chromosome of the father and are therefore all affected. The sex-linked dominant hypothesis also predicts that half the progeny of an affected

TABLE 36-6 DATA ON FOUR KINDREDS OF HYPOPHOSPHATEMIC PATIENTS

SOURCE: R. W. Winters et al. [8] and J. M. Graham et al. [9]

female should be normal and half affected without regard for sex. Data on this point are also shown in Table 36-6 and demonstrate a significant deviation from the expected distribution due primarily to an excess of normal daughter. Although the complete explanation for this unexpected distribution is not clear it is noteworthy that many of the daughters scored as normal were in the first decade where the discriminant for the diagnosis of hypophosphatemia gives a larger rate of false negative diagnoses than at any other age group in either sex [9-30].

The sex-linked dominant hypothesis not only explains more adequately than the autosomal dominant mechanism the results of the authors' own studies but also offers a better explanation for the previously reported genetic data. No pedigree published by other workers is sufficiently large to reject the autosomal hypothesis with confidence but all are equally well explained by the sex-linked dominant mechanism. The latter hypothesis also accounts for the excess of affected females in families previously described. The clear rejection of the sex-linkage would be a documented instance of male to male transmission. Although there is a

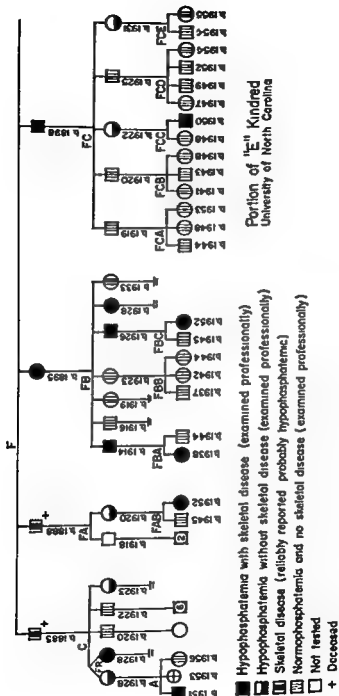

Fig 36-7 The same pedigree as that shown in Fig 36-6 scored according to the presence of hypophosphatemia (generation to generation transmission with no evidence of skipping can now be seen)

variety. A recently studied sporadic case [107] was seen in a severely affected female who showed no clinical or chemical features distinguishing her from patients with the sex-linked variety of the disease. Both parents and many relatives of this patient had no clinically or chemically identifiable related disease. The disease in this and similar patients could be the result of a new mutation or of a recessive trait or could represent a phenocopy.

## TREATMENT

The treatment of vitamin D-resistant rickets is highly individualized; it must be based on recognition not only of the age and growth potential of the patient and the severity of his skeletal disease but also of the very real risks of hypervitaminosis D.

### Vitamin D Therapy

It is in children with overt bone disease that the need for therapy is most pressing. The general plan of therapy is to start with a dose of vitamin D<sup>1</sup> of 25,000 to 50,000 I.U. daily. This is then increased by increments of 25,000 I.U. per day at intervals of 1 month to 6 weeks. Increases are determined by chemical evidence (principally a falling level of alkaline phosphatase in the serum) or radiographic evidence of healing. The dosage necessary to effect clear-cut healing is variable but is generally of the order of 150,000 to 250,000 I.U. per day. Once healing has been initiated, there is no assurance that the dose may remain constant; subsequent alterations are often necessary in order to avoid reactivation on the one hand or cumulative vitamin D poisoning on the other.

The risks of hypervitaminosis D are considerable. In some patients the effective therapeutic dose lies in the frankly toxic range. In order to avoid serious degrees of hypercalcemia, continuous medical supervision is mandatory and should include a careful search for signs and symptoms of hypercalcemia, serial measurements of serum calcium, and frequent urinalyses and estimations of blood urea nitrogen. Mild but significant hypercalcemia is often unaccompanied by objective signs and clear-cut symptoms. The Sulkowitch test for calcium in the urine is not of great value in the early recognition of vitamin D poisoning, but it may be

<sup>1</sup> Vitamin D (calciferol) is most widely used. Vitamin D is also effective as is dihydrotachysterol (A.T.10) but the latter two agents are not preferred because of expense and relative unavailability. The fact that dihydrotachysterol in doses which increase the intestinal absorption of calcium [8-11] will heal vitamin D-resistant rickets whereas its effectiveness in healing ordinary rickets is poor compared with vitamin D is further evidence for the view that the corrective action of these sterols in vitamin D-resistant rickets is a non-specific effect on calcium absorption. Consistent with this view is the healing action of dihydrotachysterol in vitamin D-deficiency rickets due to a low-calcium diet in rats [153].

single report suggesting this occurrence [10] the mother of the affected boy was not examined for hypophosphatemia.

In the first kindred studied by Winters et al [7, 8] a marked difference was observed between heterozygotes and hemizygotes with respect to the severity of bone disease. Hypophosphatemic males nearly always had obvious rickets or postrachitic deformities while hypophosphatemic females tended to have minimal skeletal involvement. In general this difference has been confirmed in the three pedigrees subsequently studied [9]. A summary of these findings appears in Table 36-7. Although exact rating of severity of bone disease is admittedly difficult, there can be little doubt about the tendency of males to be more severely affected than females.

TABLE 36-7 CLASSIFICATION OF HYPOPHOSPHATEMIC PERSONS BY SEXES ACCORDING TO SEVERITY OF BONE DISEASE

|         | Int | Mild | Moderate or severe | Total |
|---------|-----|------|--------------------|-------|
| Males   | 2   | 1    | 27                 | 30    |
| Females | 36  | 2    | 10                 | 48    |
| Total   | 38  | 3    | 37                 | 78    |

SOURCE: From studies of four kindreds by R. W. Winters et al [8] and J. B. Graham et al [9]. Classification made according to the general criteria used in [8].

In searching for an explanation for these differences statistical comparison of the levels of serum phosphorus was made between the various subgroups of heterozygotes and hemizygotes in the E kindred. In order to make any valid comparison of this type the data were age adjusted. Males in various age groups had lower levels of serum phosphorus than females in the corresponding groups. These differences although statistically significant were small. The largest was 0.47 mg per 100 ml between affected male and female children. In view of the uncertainties about the method of age adjustment the significance of these differences must remain uncertain.

The relative immunity of the female from severe skeletal disease has at least two possible explanations: (1) the normal allele may modify the action of the abnormal gene so that the female escapes severe bone disease because of heterozygosity; (2) the relative immunity of the female is a factor operative in that sex independent of gene dosage. Since there is no proved instance of a homozygous female this problem remains unresolved.

Some previous authors have reported cases of resistant rickets in which both parents were clinically normal (cf Winters et al [8] for review). In no instance have the parents been examined chemically.

Not all cases of vitamin D-resistant rickets are of the sex-linked

The treatment of osteomalacia should proceed along the lines outlined above for the treatment of affected children

In affected adults without osteomalacia the problems are those of residual deformities and the secondary arthritic complications Treatment with vitamin D is not indicated for these problems

#### *Treatment of Asymptomatic Hypophosphatemia*

There would seem to be little reason to treat patients with asymptomatic hypophosphatemia If it could be shown that treatment with vitamin D improved the growth of such children then therapy might be considered

### PREVENTIVE MEASURES

Once the mode of inheritance of the trait has been determined in a particular family the affected individuals and their spouses should be fully informed of the nature of the transmission of the gene as well as the chances and probable consequences of having a child with the disease Potentially affected progeny of such a mating should then be studied as early as practicable in order to establish the genotype on the reasonable assumption that institution of therapy may prevent serious degrees of deformity As noted earlier (see Hypophosphatemia above) the detection of hypophosphatemia is difficult in a young infant The diagnosis can be made or excluded with confidence only by obtaining multiple determinations

### SUMMARY

1 Familial hypophosphatemia and vitamin D-resistant rickets is a disorder in which the most distinctive features are hypophosphatemia and diminished renal tubular reabsorption of inorganic phosphate

2 The inheritance pattern is that of sex linked dominance with complete penetrance

3 The rickets or osteomalacia which may develop is not responsive to usual therapeutic doses of vitamin D but can be healed with massive doses of the vitamin

4 Children with bony involvement probably have abnormally low absorption of calcium from the gastrointestinal tract This responds only to large amounts of vitamin D a response similar to the effects of large doses of vitamin D on intestinal absorption of calcium in normal individuals

5 Healing of the rickets can be initiated by measures which do not involve vitamin D such as immobilization or administration of large amounts of phosphate It thus appears that the bony involvement is secondary to the disorder in phosphate metabolism rather than to a lack of a direct action of vitamin D on bone

helpful to have the parents perform the test regularly to focus their attention upon this ever present problem

In most instances careful adjustment of the dosage of vitamin D is successful in controlling the active rachitic process. As healing occurs the level of alkaline phosphatase in the serum falls to normal. Phosphorus balance becomes positive but serum phosphorus does not often rise to clearly normal values. At first glance this may seem to contradict the hypothesis that hypophosphatemia is a dominant determinant of bone disease. However the experiments of Yendt and Howard [159] provide an explanation. They found that transient increases in the level of phosphate in rachitic rats may be sufficient to initiate calcification, which continues even though the ambient concentration of phosphate is again reduced to levels associated with rickets.

Healing of the rickets is often associated with some improvement in the severity of the deformities although in cases with serious degrees of deformity subsequent osteotomy may be indicated. Surgical correction should be undertaken only after the active process is fully controlled. *Before and during the period of immobilization the dosage of vitamin D must be greatly reduced or eliminated and then reinstituted with mobilization.*

Another major unsolved problem in children is that although the rachitic process may be optimally controlled by vitamin D, the expected increase in the rate of linear growth does not often occur and the patients remain dwarfed. The possibility that continuing hypophosphatemia limits linear growth independently of its effect upon the rachitic lesion deserves further study.

### *Other Therapeutic Measures*

It has been shown [114] that adding inorganic phosphate to vitamin D therapy may increase phosphate and calcium retention restoring the serum phosphorus concentration to normal. The administration of phosphate will initiate healing even in the absence of vitamin D [119]. However after more extended observations Fraser has concluded that long term phosphate therapy has no proved place in the management of vitamin D-resistant rickets and may even be harmful [95].

### *Treatment of Affected Adults*

The rarity of overt osteomalacia in adults with hypophosphatemia and a history of vitamin D-resistant rickets is remarkable. In the large kindred studied by Winters et al [8] there were 23 adequately studied hypophosphatemic adults. Only 2 of these had evidence of osteomalacia in the form of single pseudofractures. A few affected adults with serious degrees of osteomalacia have been reported by others [5, 28, 91, 92, 101].

6 One of the leading explanations proposed for the disease is that there is an intrinsic defect in the function of the renal tubular cells. If so the defect is highly specific for it is not associated with any other known tubular defect. Furthermore the aminoaciduria which accompanies vitamin D-deficiency rickets is not found in individuals with familial hypophosphatemia.

7 The second leading explanation is that there is overactivity of the parathyroids, secondary to diminished intestinal absorption of calcium which depresses renal tubular reabsorption of phosphate. If so, the compensatory adjustment is remarkably exact for serum calcium concentration is almost always normal and hyperparathyroidism is not detectable clinically.

8 Studies of the quantitative aspects of tubular reabsorption of phosphate in relation to parathyroid function to the action of vitamin D and to the reabsorption of other substances which may affect phosphate reabsorption are needed to clarify the fundamental abnormality in familial hypophosphatemia.

9 From genetic considerations it is possible to predict individuals likely to develop the disorder, and to take the necessary steps toward early detection and prevention of the deforming features of this disease.

## Chapter 37

### The Syndrome of Osteomalacia, Renal Glycosuria, Aminoaciduria, and Hyperphosphaturia (The Fanconi Syndrome)

---

Alexander Leaf

The main features of this syndrome upon which there is general agreement are rickets or osteomalacia resistant to vitamin D in usual doses, glucosuria, generalized aminoaciduria, and hyperphosphaturia in spite of normal or reduced plasma concentrations of the  $\alpha$  constituents and usually chronic acidosis and hypopotassemia. Beyond these cardinal features one finds much disagreement and confusion in the literature pertaining to this rare disturbance. Recent awareness that multiple etiologies may reproduce these cardinal features and that each feature may occur separately or in various incomplete combinations indicates that the appellation *syndrome* rather than *disease* is appropriate. To avoid ambiguity in the present writing eponyms will be avoided and the italicized term *syndrome* will be used to apply to the complete constellation of features as defined above.

#### HISTORICAL RESUME

The history of the recognition of this *syndrome* has been confused by uncertainty as to just which features it encompasses and which eponyms should be applied to it. Not all the features recognized today as part of the *syndrome* were appreciated by earlier workers. Their case reports therefore seem fragmentary and incomplete making it difficult to trace the historic lineage accurately.

In 1903 Abderhalden [1] found by chemical assay excessive amounts of cystine in various tissues at post mortem examination of a 21 month old Swiss infant who died of inanition. Crystals identified as cystine

were visible macroscopically in the liver and spleen. Two siblings had died previously of a similar ailment, and the urine of two living siblings contained excessive cystine, as did to a lesser extent the urines of the father and paternal grandfather. He thus labeled the disorder a familial cystine diathesis.

In 1924 Lignac [2-3] a Dutch pediatrician described three similar cases in children 14 months old and 2 and 3 years of age. Clinically all three had severe rickets, renal disease, dwarfism, and progressive wasting. Pathologically all showed widespread deposits of cystine in the tissues and nephritis, and one child reportedly had cystine stones in the renal pelvis and ureter. Lignac also noted the familial incidence of the disease, as a sister of one of his patients was afflicted. Two further cases were reported from England by Russel and Barrie [4] in 1936. One child had rickets with a low normal serum phosphate concentration but no cystine crystalluria. Both he and the second child probably died in uremia, since post mortem examination revealed extensive glomerular and tubular damage as well as cystinosis. The following year Beumer [5] added albuminuria and glycosuria to the clinical picture and demonstrated in his case that the nonprotein nitrogen level became elevated only terminally. Thus, cystine storage disease came to be recognized.

Meanwhile in 1931 Fanconi [6] briefly described rickets and stunted growth in a child with albuminuria and glycosuria. In 1933 deToni [7] reported a dwarfed child with vitamin D-resistant rickets and spontaneous fractures who showed a low serum phosphorus concentration, acidosis, glycosuria, and albuminuria. With a similar case reported by Debré [8] in 1934, the one of deToni and two more of his own, Fanconi [9-10] in 1936 established a syndrome of nephrotic glycosuric dwarfism with hypophosphatemic rickets. Beumer and Wepler [11] in 1937 surmised that cystinosis and the Fanconi syndrome were identical, and this seemed proved when at necropsy one of Fanconi's original cases showed cystine deposits in his tissues [12]. The extreme form of this view was supported by Bickel and associates [14] who concluded that Lignac's disease (cystine storage disease) and Fanconi's syndrome of childhood (nephrotic glycosuric dwarfism) are one and the same disease, and at the present time this disease cannot be identified with similar syndromes in which cystine storage has been excluded. Though it is generally accepted today that the two conditions are similar, this point of view is opposed by deToni [13] who believes that when cystinosis and the syndrome of renal glyco-amino-phosphaturia coexist, the latter probably represents a complication of the former. DeToni would therefore create two separate syndromes: the Alderhalden-Kaufmann-Lignac syndrome to designate cystine storage disease, and the deToni-Debré-Fanconi syndrome to designate rickets or osteomalacia with renal glyco-amino-phosphaturic diabetes. The nomenclature is further confused by the use of various

combinations of eponyms for various features of the syndrome. Many case reports of this *syndrome* are summarized in the monographs of McCune, Mason, and Clarke [15], Bickel, Smallwood, Smellie, and Hickmans [14], and Eberlein [16].

The aminoaciduria in the *syndrome* was first suspected by Fanconi [10] when he found an increased organic aciduria. McCune, Mason and Clarke [15] were the first to demonstrate that the organic aciduria was in fact largely attributable to amino acids.

It has become evident that the *syndrome* is not restricted to infancy or childhood but may present initially in adult life with the same cardinal features. Cystine deposits in the tissues have not as yet been described in the adult cases although they are commonly an associated finding in the childhood form. The adult form of the *syndrome* has recently been reviewed by Walsh and Lingle [17], who in 1957, collected 18 cases from the literature.

## CLINICAL FEATURES

In the infant the disease characteristically begins after a normal postnatal period of 4 to 6 months. Failure to grow, often bouts of vomiting and unexplained fever, a severe form of rickets resistant to the usual doses of vitamin D, chronic acidosis, polyuria and dehydration dominate the clinical picture. In spite of glucosuria and phosphaturia the blood glucose concentration is not elevated and the serum phosphorus level is usually normal or low, but it may rise terminally with renal glomerular failure. In spite of systemic acidosis the urine is relatively alkaline and has a high content of ammonium. A generalized aminoaciduria usually involving excessive excretion of 10 or more amino acids, is found [18]. The high cystine excretion is just one facet of the more generalized aminoaciduria and need not occur even in the presence of large losses of other amino acids. This urinary amino acid pattern is therefore quite distinct as are the other clinical features from that of 'cystinuria,' in which excessive urinary losses of only cystine, lysine, arginine and ornithine are found (cf Chap. 42).

The familial incidence of the condition has been noted and will be examined below. The prognosis has generally been poor. Few patients survive more than a few years but deLam [19] recently reported 'a case of the syndrome' where the patient after having presented grave manifestations in infancy nevertheless reached adult age and may be looked upon as having made a complete recovery. Death is usually due to progressive renal failure or intercurrent infection. Post mortem examination sometimes reveals crystals of cystine extensively deposited throughout the body and cystinosis may be detected during life by examination of the conjunctiva and cornea with a slit lamp [20, 21] and of the bone

marrow [21-22] As indicated above controversy continues regarding the relationship of cystine storage disease to this *syndrome* Cystine storage definitely does not occur in all instances In 11 recorded autopsies on patients with glycosuria and rickets collected by McCune et al [15] cystine deposits were recognized in 4 and their presence was suspected in a fifth Because cystine crystals may easily be lost in fixation of tissues or may be unrecognized, it is impossible to ascertain the exact incidence of cystine storage at present It seems highly likely that the *syndrome* may occur in the absence of cystinosis in fact, cystinosis has not yet been described in the adult cases } ✓

In the adult the *syndrome* has the same features as in the infant, i.e., osteomalacia with multiple fractures and pseudofractures hypophosphatemia with hyperphosphaturia usually elevated alkaline phosphatase level generalized aminoaciduria with normal concentrations of amino acids in the serum and renal glucosuria Frequently there are albuminuria alkaline urine and mild or severe systemic acidosis occasionally hypokalemia and hypouricemia are present Crippling bone disease with pain and deformities dominates the clinical picture Glomerular filtration rate may be normal or only moderately reduced but the usual cause of death is glomerular insufficiency with retention of nitrogenous waste products and uremia

## PATHOPHYSIOLOGY

### CALCIUM AND PHOSPHORUS METABOLISM

Rickets or osteomalacia the most prominent clinical feature of the *syndrome* early focused attention on the derangement of calcium and phosphorus balance

A reduced serum phosphorus concentration has been a common finding although with terminal glomerular failure the level rises to normal or higher The serum calcium levels are usually normal while the alkaline phosphatase concentration is elevated The chemical features of osteomalacia [23] are therefore present in the blood and the bone disease has been repeatedly shown both radiologically and histologically to be rickets in the growing child and osteomalacia in the adult

Hyperphosphaturia has been considered an important feature of this condition [15-24-27] In addition elevated renal clearances of phosphate have been reported [28-30] indicating simply that renal excretion of phosphate remains relatively high despite the low serum phosphate concentration From the available evidence the usual causes of an increased renal clearance of phosphate do not seem to explain the findings in the *syndrome* The usual causes include primary and secondary hyperparathyroidism

Primary hyperparathyroidism seems definitely excluded by the absence

of hypercalcemia [17] and the presence of osteomalacia rather than osteitis fibrosa cystica. The reported findings in the parathyroid glands at necropsy are difficult to interpret but tumors have not been described [18], and mention of normal parathyroids has been made [9 10 31]. Surgical biopsy specimens of parathyroid glands from two of Hunter's cases were interpreted as normal [32].

Secondary hyperparathyroidism is not so readily excluded, histologically its presence or absence may be very difficult to ascertain. By definition this condition refers to a compensatory state requiring persistence of some *physiologic* stimulus to increase parathyroid activity above that normally required to meet the needs of the body. Albright and Reifenstein have considered a reduction in the concentration of serum calcium to constitute the effective stimulus [23], resulting in the following sequence of events: decreased serum calcium concentration  $\longrightarrow$  increased parathyroid activity  $\longrightarrow$  increased renal clearance of phosphate  $\longrightarrow$  reduced serum phosphate  $\longrightarrow$  return of serum calcium concentration toward normal.<sup>1</sup> To establish the presence of secondary hyperparathyroidism it is necessary to demonstrate a cause for a reduced serum calcium level. The usual cause is either an increased calcium excretion by the kidneys or a reduced absorption of calcium from the gut. However no such impairment in calcium metabolism can be traced in all cases of the *syndrome*.

Primary hypercalcaemia has not been noted and values for calcium excretion within a low or normal range are reported [15 28 30]. Furthermore the clinical picture bears no resemblance to that of idiopathic hypercalcaemia in which renal stone formation is the cardinal finding [33]. Hypercalcaemia is also a feature of renal tubular acidosis [23] and some patients with the *syndrome* have definite hyperchloremic acidosis [15 29] but others have severe osteomalacia with increased phosphate clearance in the complete absence of systemic acidosis [28 31 34] and with normal ability to excrete an acid load [25]. Albright and Reifenstein [23] postulated that the increased anion excretion imposed by the aminoaciduria would overtax the hydrogen ion excretory mechanisms (fixed cation-sparing mechanisms) of the kidney so that an increased calcium excretion would result causing demineralization of bone. This was an *a priori* assumption made admittedly without any cases to study. This view is disproved by the evidence that the amino acid excretion in the *syndrome* usually contributes only a small additional load of acids to those requiring excretion that severe bone disease may be present when aminoaciduria is a minimal feature [28 34] and that the renal acidifying

<sup>1</sup> The secondary hyperparathyroidism seen in chronic azotemic renal failure need not be considered here since an elevated rather than reduced serum phosphorus level is present. The renal clearance of phosphate is decreased not increased and the resulting osteodystrophy is not rickets or osteomalacia [23].

mechanisms of the kidney are not always overtaxed as evidenced by a normal response to further loading with strong acids [28]. Thus excessive renal loss of calcium can be excluded as initiating the disturbance in calcium and phosphorus metabolism.

An impaired absorption of calcium from the intestines is not a constant finding either. A lack of vitamin D in the usual doses is certainly not a factor. Treatment of the bone disease with usual or even moderately large doses of vitamin D provides inconspicuous or ephemeral benefit [10]. Normal blood levels of vitamin D [35-36] were reported in the case of Guild, Pierce and Iibenthal [24]. The normal levels of serum calcium together with the usually normal or even high levels of urinary calcium excretion [10] would seem to exclude simple failure of intestinal absorption of calcium. Not all investigators, however, agree on the last point. Bickel and associates [14] have interpreted their own results and those in the literature as indicating impaired intestinal absorption of calcium as the major cause of the bone disease. Recently Davies et al [37] have likewise reported a disturbance in intestinal absorption of calcium and phosphorus together with a very low urinary calcium excretion in a case of the syndrome.

Kyle and associates [28] have made important observations in an adult with the syndrome. By means of balance studies they showed (Fig. 37-1) the following: (1) Without therapy and while on a diet containing 1,200 mg calcium and 1,900 mg phosphorus daily, the patient was in negative calcium and phosphorus balance. The urinary phosphorus level was high, but there were normal amounts of calcium in the urine. Serum calcium concentration was normal and serum phosphorus low. (2) Alkali therapy with Shohl's solution (sodium citrate-citric acid mixture) had no effect on the calcium or phosphorus balance, a finding consistent with the complete absence of acidosis in their case. (3) 100,000 units of vitamin D daily improved calcium balance by decreasing fecal calcium loss, but urinary calcium excretion was not reduced and urinary phosphate excretion rose still higher. (4) Supplementary intake of neutral phosphate resulted in a positive phosphate balance with increased serum phosphorus concentration, although excretion of phosphate in the urine rose and most significantly there was a decrease in urinary calcium excretion. In this one case they were therefore able to exclude acidosis, vitamin D deficiency and an intestinal absorption defect as the cause of osteomalacia. Suggestive evidence was further presented that the hyperphosphaturia was not secondary to hyperparathyroidism, since the patient responded normally to the intravenous administration of parathyroid hormone with a further large phosphate diuresis. This would not be expected had excessive circulating parathyroid hormone initially been responsible for the hyperphosphaturia. These metabolic studies thus speak in favor of a primary defect in renal

tubular reabsorption of phosphate, a view suggested repeatedly in the past [10, 12, 27, 31, 35]

The absence of any apparent secondary cause for the increased renal clearance of phosphate had led most workers to postulate a primary defect in the renal tubular conservation of phosphate. It should be

Fig 37-1 Results of the balance study showing calcium phosphate and nitrogen changes in a 42-year-old male with the syndrome (Data of Kyle Meroney and Freeman [28] reproduced by permission of the Journal of Clinical Endocrinology and Metabolism)

pointed out however that in the case carefully studied by Milne, Stanbury and Thomson [29] there occurred an apparent decrease in the high renal clearance of phosphate consequent to successful therapy of the bone disease with vitamin D and alkali. This finding suggests that the high renal clearance initially present in their case was a secondary rather than a primary defect. Correction of acidosis together with improvement of gastrointestinal absorption with vitamin D makes it difficult to evaluate the single clearance they report after therapy since

correction of acidosis alone might have reduced the phosphate clearance. The studies presented by Anderson, Miller and Kenny [34] also showed a drop in phosphate clearance when therapy with alkali and vitamin D improved calcium and phosphorus balances in their case. Thus with an increase in serum phosphorus concentration from about 2.0 to 3.5 mg per 100 ml the urine phosphorus rose only from 1.7 to 1.9 gm per 24 hr. Salas, Powers, Ulrich and Hayles [39] have confirmed this finding in two patients in whom balance studies were done. Whereas alkali administration with correction of acidosis failed to correct the hypophosphatemia or consistently alter the balances of calcium or phosphorus, administration of vitamin D in doses of 400,000 units daily for 30 days produced marked improvement in both patients. As a result of a marked decrease in fecal phosphorus and only a slight increase in urinary phosphorus during administration of vitamin D the phosphorus balance became positive and the renal clearance of phosphate dropped 37 and 44 per cent, respectively in their two cases.

These changes in renal phosphate clearance with repletion of body calcium and phosphorus stores are those classically ascribed to relief of secondary hyperparathyroidism [23]. However, an initial cause for secondary hyperparathyroidism can not be elicited in all cases of the *syndrome*. The alternate postulate that the phosphate loss is due to a primary defect in the renal tubular conservation of phosphate must still be retained. This defect perhaps may be specifically corrected by vitamin D in very large doses and indeed large doses of vitamin D may also have a favorable influence on other associated tubular defects (see below). Such a renal tubular defect might be modified in individual cases, however, by the existence of other factors known to affect calcium and phosphorus metabolism.

Davies et al. [37] make the interesting suggestion that a disturbance in intestinal as well as in renal tubular reabsorption may exist. The high intestinal phosphate would then secondarily interfere with intestinal absorption of calcium to explain the finding of a low urinary calcium excretion in some cases of the *syndrome*. Vitamin D, according to this view, corrects the intestinal as well as the renal defect in phosphate absorption, thereby improving the calcium balance together with the phosphorus balance. The secondary hyperparathyroidism induced by impaired intestinal absorption of calcium would thus be relieved.

#### ACIDOSIS AND ASSOCIATED ELECTROLYTE DISTURBANCES

Although not a cardinal feature of the *syndrome* as defined above, acidosis is a common finding in both the infantile and adult types. In untreated cases the acidosis may be severe. The serum  $\text{CO}_2$  content may fall as low as 9 mEq per liter [14]. The disturbances in acid-base balance have been carefully studied by Linder, Bull and Grayce [38] in an adolescent

by Milne and associates [29] Kyle and associates [28] and Sirota and Hammerman [30] in adult cases and by Bickel and associates [14] in several cases of the infant and childhood form.

The earliest thorough investigation into the acid base metabolism in the syndrome was that of Linder Bull, and Grayce [35]. Studying a 13-year-old girl they found the following: (1) The serum was of normal reaction but with slightly reduced bicarbonate concentration ( $c$  20 mEq per liter). (2) The rate of organic acid excretion was two to three times normal. (3) Following administration for 4 days of 2.5 mLq hydrochloric acid per kilogram of body weight per day, chloride excretion rapidly increased but ammonium excretion was distinctly subnormal, and titratable acids did not increase as expected. The excretion of the administered chloride was therefore, accompanied by a large loss of fixed cations.

The patient of Milne, when untreated, showed the typical picture of hyperchloremic acidosis. The serum bicarbonate was 14 mEq per liter (normal 20 to 30), the serum chloride was 118 mEq per liter (normal, 97 to 103) and the blood pH 7.1 to 7.3 (normal 7.35 to 7.43). The glomerular filtration rate as indicated by inulin clearance was reduced to 31 ml per min, a value approximately one-third to one-quarter the expected normal value. The plasma urea concentration was not elevated. An abnormal loss of bicarbonate in the urine was demonstrated. Even with the serum bicarbonate concentration reduced to 14 mEq per liter the daily excretion of bicarbonate in the urine was 20 mEq. Since at this plasma level all bicarbonate filtered is normally reabsorbed [40] the finding constitutes definite evidence for a reduced renal threshold for bicarbonate. Such bicarbonate wastage is a known feature of renal tubular acidosis [41]. It was not associated with an absolute loss of reabsorptive capacity for bicarbonate reabsorption was found to increase as in the normal person when the serum bicarbonate excretions rose with alkalinizing therapy.

The failure of the patient to excrete an acid urine was attributed to the presence of bicarbonate in the urine. Only after all the bicarbonate is reabsorbed from the tubular urine does the further excretion of hydrogen ions into the distal tubular urine succeed in making the urine strongly acid. When reabsorption of bicarbonate proximally is faulty so that bicarbonate is present in the distal tubular urine, hydrogen ion secretion by the distal tubule serves only to convert bicarbonate to carbonic acid. As the carbonic acid that is formed undergoes rapid decomposition to volatile carbon dioxide and neutral water the urine is not rendered acid.

Although Milne and associates found the rate of ammonium excretion in the urine to be normal or high for the pH of the urine, ammonium production was nonetheless totally inadequate in a biologic sense for the degree of systemic acidosis. The finding of an ammonium concentra-

tion relatively high for the urine pH would at present be ascribed to the concurrent potassium deficiency [47]

The disturbance in acid base regulation noted by Sirota and Hamerman [50] and their studies of this disturbance in their case were very similar to the observations of Milne and associates [9]. Their patient also had a hyperchloremic acidosis with urinary wasting of bicarbonate and impaired ammonium production.

All 14 of the children with the *syndrome* studied by Bickel and associates [14] were acidotic as indicated by a lowered  $\text{CO}_2$  combining power of the plasma. In each the degree of acidosis varied considerably quite apart from treatment and normal or only slightly lowered  $\bar{\text{CO}}_2$  values were found occasionally in almost all. Several of their patients were found to excrete large quantities of bicarbonate in the urine despite acidosis with reduced plasma  $\text{CO}_2$ . Defective ammonium formation and titratable acid secretion in some of the children likewise indicated either an inadequate or completely absent response to the administration of acid. Organic acid excretion was increased.

The findings of the above workers thus indicate a complex disturbance in renal function as the cause of the acidosis with defective tubular reabsorption of bicarbonate playing the major role and defective ammonium production, reduced titratable acidity and increased excretion of organic acids all contributing. As evidence of normal renal responsiveness to acidosis in this *syndrome* a patient of Fanconi [10] and one of McCune [15] are often cited to show that urine pH may be low while ammonia production and titratable acidity are high. In McCune's patient the plasma bicarbonate which was between 10.9 and 18.7 mEq per liter indicated severe acidosis. With such reductions of serum bicarbonate one might expect that even with a diminished tubular reabsorptive capacity for bicarbonate all of the decreased amounts of bicarbonate filtered would be reabsorbed thereby permitting production of an acid urine with increased ammonium and titratable acids. Thus Bickel et al. [14] noted that in one of their patients the bicarbonate loss stopped completely during a period of acid administration. At the same time the urine pH dropped from 14 to 3.8 while the plasma  $\text{CO}_2$  fell to the alarmingly low level of 7.3 mEq/l. At the present time it may be justifiably concluded that even when the renal hydrogen-excreting mechanisms appear to be functioning normally the response is totally inadequate for the degree of systemic acidosis. If recognition is given to the expected absence of bicarbonate in the urine when the patient is severely acidotic it seems that the renal disturbances together with the moderate increase in organic acid excretion mentioned adequately account for the acidosis.

Ketonaemia has been a common finding in this *syndrome*. It is not surprising in view of the renal glucosuria and inanition but has not been

proved in any instance to be of quantitative importance in producing acidosis

The impression should not be left that acidosis or impaired renal mechanisms for hydrogen ion secretion are essential parts of the disease process. In the well-documented case of Kyle et al [28] the patient had a normal plasma bicarbonate and in response to an acid load of 130 mEq ammonium chloride daily for 3 days produced as acid a urine with as high a titratable acidity as did a normal control similarly treated and an even higher ammonium content than the control. The bone disease and other features of the *syndrome* were nevertheless all present. The variability in the number and severity of the features apparent in any given case will be considered further below.

A deficiency of potassium which is causally related to the defect in hydrogen ion excretion has been generally appreciated since the study of Milne et al [29] although Linder and associates previously [38] commented on the loss of sodium and potassium in association with the production of dehydration and symptoms of potassium deficiency. Case histories of this *syndrome* refer frequently to unexplained bouts of weakness, paralysis and collapse. An interesting occurrence termed "dextrose shock" has been noticed. This consists of severe and sudden peripheral collapse during sugar tolerance tests. Both Debré [8] and Fanconi [10] witnessed such episodes in conjunction with the oral administration of dextrose for glucose tolerance tests. Debré's patient became restless and pallid and then lapsed into fatal coma. In neither of the two patients of Fanconi did the episode prove fatal. These episodes are most probably the result of hypokalemia, a finding repeatedly noted in this *syndrome* [14, 17, 29]. In addition to the weakness, paralysis and collapse, potassium depletion is undoubtedly responsible for at least two other common findings, polyuria and, at post mortem, vacuolar changes affecting the renal tubular epithelium. Polyuria with isosthenuria had been frequently noted and in some instances shown to be resistant to antidiuretic hormone [38]. This is characteristic of the nephropathy of potassium deficiency [42]. Recently Davies et al [37] have demonstrated improvement in urinary acidification following correction of potassium deficiency in their patient. They considered the potassium depletion to be primary rather than secondary to the disturbance in acid base regulation and hence to represent a separate tubular reabsorptive defect.

#### GLUCOSURIA

Glycosuria was recognized early in the delineation of this *syndrome* and has remained one of its most definite and least controversial features. The reducing substance in the urine was found to be glucose by Fanconi [9, 10] and subsequently by others. It is of renal origin, i.e. the result of a lowered renal threshold for glucose. In the few instances in which diabetic

like glucose tolerance test results have been observed preceding carbohydrate depletion was probably responsible. In many instances cases have been incorrectly diagnosed and treated with insulin. The glucosuria is variable, ranging from mere traces to 4 to 5 gm per 100 ml [14-15]. The elimination of sugar is characteristically continuous at least in the more severe forms of the syndrome but it may be intermittent and not infrequently will disappear terminally.

The presence of glucosuria has had a special significance in this syndrome in helping to localize the site in the nephron where the functional impairment resides. The findings of Richards [43] are generally accepted as demonstrating that glucose reabsorption occurs in the proximal tubule. Hence the presence of renal glucosuria has constituted a strong argument in favor of placing the disturbance in the proximal tubule. The location of the disturbance in the kidney will be considered in greater detail below.

### AMINOACIDURIA

Aminoaciduria is the most recently recognized feature of the syndrome. Although suspected by Fanconi [10] it was not proved until the work of McCune and associates [15]. It has been investigated in detail only since the techniques of chromatography were applied to the problem notably by Dent [18] who since 1947 in a series of studies [18-44-46] has characterized the main features of the aminoaciduria.

The normal individual excretes some 200 to 400 mg amino acids daily [47]. Amino nitrogen constitutes less than 3 per cent of the total urinary nitrogen [18]. Figure 37-2A and B show the urinary pattern of amino acids from a normal infant and adult respectively. The trace amounts of amino acids in normal subjects are to be contrasted with the high excretion rates shown by a child and adult with the syndrome (Fig 37-3A and B respectively). These figures illustrate the main features of the aminoaciduria: (1) It is a generalized aminoaciduria involving usually 10 or more amino acids. (2) The pattern of amino acid excretion is variable from case to case but seems to remain quite constant with time in any individual case [46]. (3) Cystine excretion may be increased or normal even in the presence of cystinosis. Renal calculi of cystine have so far been reported in only one case [48]. These features distinguish the aminoaciduria sharply from that seen in cystinuria in which the excretion of only four amino acids is increased and these are always the same (cystine, lysine, arginine and ornithine) [49-51] as shown in Fig 37-4.

The generalized aminoaciduria is reminiscent of the overflow type seen in severe liver disease [52-53]. However, Dent has demonstrated that the plasma amino acid concentrations are normal or low [18] rather than elevated as in liver disease. Harper and associates [54] have also reported essentially normal plasma levels for several amino acids that were present

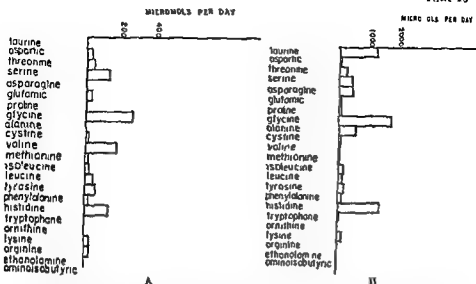

Fig 37.2 A The daily amino acid excretion in the urine of a normal infant (according to Jonxis [73]) B The daily amino acid excretion in the urine of a normal adult (Data of Harrison and Harrison [83] reproduced by permission of the Journal of the American Medical Association)

Fig 37.3 A The daily amino acid excretion in the urine of a child with cystine storage disease and the syndrome (From Harrison and Harrison [83]) B The daily amino acid excretion in the urine of an adult with the syndrome (Data of Evered [47] recalculated by Harrison and Harrison [83] and reproduced by permission of the Journal of the American Medical Association)

in excess in the urine. Although Dent's findings were contested by Bickel and Smellie [21] who reported levels 50 to 100 per cent above the normal range. Evered has recently [47] reexamined the problem with the more precise method of quantitative ion-exchange column chromatography and has convincingly supported Dent's results. Thus the renal clearance

of amino acids: high in the *syndrome* and a defect in renal tubular reabsorption would seem to be responsible for this feature.

Because knowledge regarding the normal tubular mechanisms for amino acid transport is only fragmentary the defect responsible for the aminoaciduria in the *syndrome* is not understood. Latham, Baker and Bradley [55] found a gross aminoaciduria during fastings in their patient with the *syndrome*. However during an intravenous infusion of amino acids (hydrolyzate of fibrin) the increase in amino acids in the urine was not in excess of that occurring normally during a similar infusion. They suggested that the defect in tubular reabsorption of amino acids may involve only a small percentage of the nephron population. This conclusion is at variance with both the reported widespread distribution of the morphologic changes in the kidney (see below) and the results of Robson and Rose [56] who found a high initial clearance of cystine in their patient which rose only slightly following infusion of lysine to equal the clearance of inulin. Beyer and associates [57] have studied competition for reabsorption of various amino acids by the renal tubules and indicated that at least three separate transport systems are present in the dog for tubular reabsorption of different amino acids. If these studies in the dog are applicable to the human kidney patients with the *syndrome* lose amino acids from all three groups. Little [58] in studies also with the dog demonstrated that the reabsorptive processes of the tubules of amino acids are distinct from those involved in glucose absorption.

## MORPHOLOGIC CHANGES

Only recently has any lesion been described at necropsy which appears to have some specificity to this disorder. There are reasons to believe that a lesion in the proximal renal tubule could most easily account for the renal disturbances of the *syndrome*. Thus there has been great interest in the report in 1953 of Clay, Darmady and Hawkins [59] of a characteristic lesion affecting this portion of the nephron. By using a microdissection technique to isolate individual nephrons these workers ob-

served two apparently characteristic types of lesions present in the kidneys of two patients with the *syndrome* (1) The swan neck deformity illustrated in Fig 37 5B, was present 100 times out of 101 consecutive nephrons examined at random. In this lesion normal glomeruli are attached to a narrow neck in which the epithelium is of a low cuboidal form for a distance of 0.3 to 1.0 mm. Further down the epithelium suddenly expands into the height and shape of the normal proximal tubule (Fig 37 5A) but differs from it in possessing a greater translucency. (2) The second change is a shortening of the whole proximal convoluted

Fig 37-5 A Normal human glomerulus and proximal tubule as seen following microdissection. B Glomerulus and nephron from a patient with the *syndrome* showing the swan neck lesion affecting the proximal tubule. C Glomerulus and nephron from a patient with the *syndrome* showing the atrophy and shortening of the proximal tubule. (From Darmady and Stranack [60] reproduced by permission of the British Medical Bulletin.)

tubule including its narrow portion. The authors considered that the proximal tubules were atrophic and about one-fourth to one-half the normal length. This lesion is also shown in Fig 37 5C in which a normal nephron has been included for comparison.

More recently Darmady and Stranack [60] have reported their further experience with the microdissection technique in 11 cases<sup>21</sup> where the clinical history conformed strictly to that laid down for Lignac Fanconi disease (cystinosis).

In 8 the proximal tubule was shorter than normal and its first portion was replaced by a thin and narrow neck for about one-third of its length, i.e. the swan neck defect. The remaining 3 cases showed a hypotrophic lesion throughout the length of the proximal tubule. In the recent report two additional patients are mentioned who in life had glycosuria, phosphaturia, hypopotassemia, abnormal amino aciduria, and dwarfism but who lacked cystinosis. Both these patients showed the typical swan neck lesion. It is of special interest that one of these two patients, aged 46, had the adult form of the *syndrome* while

the remaining 12 were all of the infantile or childhood form, the oldest being 9 years of age

The absence of any associated regenerative changes in the kidneys together with the regularity and frequency of the proximal tubular lesions led the authors to the conclusion that these represented congenital defects even though the clinical syndrome often did not become manifest for some time after birth. The lesions seemed specific. They were not found in tissue obtained from a case of renal amyloidosis and were distinguished from a somewhat similar lesion described by Oliver [61] in chronic nephritis in which only a small fraction of the nephrons are affected.

Other renal lesions have been described in this *syndrome* which do not seem to be specific. Vacuolation of the tubular epithelium has been noted [16] but this is attributable to the associated potassium depletion which is often encountered in these patients and which is known to produce similar vacuolar changes [41]. Atrophic changes in the distal tubular epithelium similar to those seen in acute tubular necrosis have also been reported [59] as have varying degrees of renal fibrosis. Since progressive renal impairment with uremia is a common outcome of this *syndrome* fibrosis and loss of nephrons are perhaps to be expected at necropsy but their relationship to the structural basis of the observed renal dysfunction is difficult to ascertain. Pyelonephritis may be responsible for the progressive renal failure. Potassium depletion may in turn predispose to pyelonephritis [62] although this suggestion requires further support [42].

In addition to renal pathologic changes changes in other tissues have also been noted. Skeletal changes consistent with rickets or osteomalacia occur as expected [6]. Fatty liver and focal necrosis of the liver or cirrhosis have been noted repeatedly though not invariably. Their relationship to the remainder of the *syndrome* remains obscure [15-27]. It has been suggested that the urinary amino acid loss might be the cause of the cirrhosis [27] but evidence is lacking that such loss is of sufficient magnitude to be considered seriously as a cause of protein depletion. Cystine crystals have been reported in the tissues of many but certainly not in all the autopsy reports. The fact that Bickel and Smellie [21] were able to demonstrate cystine crystals *ante mortem* in bone marrow biopsies from all 17 of their cases suggests that a more careful search will reveal crystals in a larger fraction of cases.

## ETIOLOGY AND GENETICS

Fanconi is generally credited with the view that impairment of the reabsorptive capacity of the renal tubules without a corresponding reduction in glomerular filtration volume could account for the major features

of the *syndrome*. A tubular reabsorptive defect seems to be directly responsible for the aminoaciduria, glucosuria, phosphaturia and the tendency to excrete an alkaline urine, and secondarily responsible for the systemic acidosis and skeletal changes. The anatomic changes found by Darmady and associates [59-60] appear to provide a morphologic basis in the proximal tubule for such a defect. The proximal tubule is thought to be the site of reabsorption of glucose [43] and Fanconi [63] considers the proximal tubule to be the site of reabsorption of amino acids and phosphate as well. Hence the morphologic changes are to this extent consistent with the functional derangements.

When one asks the important next question, namely, what is the cause of the renal tubular defect, a unitarian approach to the *syndrome* is no longer tenable. The familial occurrence of this rare *syndrome* early suggested an hereditary basis for the disease. Recently, however, the renal defects associated with the *syndrome* have been recognized repeatedly under circumstances in which renal damage was clearly acquired. Harrison and Harrison [64] reported that injections of maleic acid into rats may produce renal glucosuria, phosphaturia and a generalized aminoaciduria. It had previously been demonstrated that this compound interfered with the renal excretion of acid by acidotic dogs [65]. These renal disturbances proved reversible. Spencer and Langlen [66] have reported gross glucosuria and aminoaciduria without elevated blood glucose or amino acid concentrations occurring transiently during the recovery phase of acute renal failure in a patient who suffered an extensive Lyol burn. Experimental uranium poisoning may produce glucosuria and aminoaciduria [67-68]. Gross renal aminoaciduria has been observed in lead poisoning [69-71] and in cadmium, mercury and uranium poisoning [72]. In at least one instance of lead poisoning in a child [70] the aminoaciduria was associated with glycosuria, persistent hypophosphatemia and rickets. The acquired *syndrome* in this child resolved after treatment of the lead poisoning. Vitamin D deficiency has been associated with renal aminoaciduria [73]. Of considerable interest is the association of multiple myeloma and the adult form of the *syndrome* reported recently by Engle and Wallis [74] and noted earlier by Sirota and Hamerman [30]. These clinical and experimental observations indicate that the *syndrome* may have multiple etiologies in which the common denominator is renal tubular injury with impairment especially of the systems that are important in the renal tubular handling of amino acids, glucose and phosphate.

The hereditary nature of this *syndrome* was first noted by Abderhalden [1] and has been referred to repeatedly since. Duplication of the *syndrome* in siblings and blood relationship between parents have been noted [15]. Dent and Harris [75] concluded from their study of the genetics of this *syndrome* that 'the simplest view is that we are concerned with a simple

recessive character. The difficulty of characterizing genetically transmitted traits in human disease as either simply dominant or recessive has been recently emphasized [76]. What is definite however is that this rare syndrome may affect more than one sibling and that there is a high instance of parental consanguinity [15-75]. Clarification of the genetic mode of transmission is made difficult because acquired renal tubular damage can mimic this syndrome. There also remains uncertainty as to whether individuals who develop the adult form of the syndrome have had a renal tubular defect since birth or whether the lesion itself developed only in adult life and accordingly whether the infantile and adult forms are the same disease. Dent and Harris [75] described an interesting family in which three adult siblings had biochemical abnormalities closely similar to those found in the propoitus with the adult form of the syndrome. Each sibling resembled the patient in having generalized aminoaciduria, mild acidosis and hypophosphatemia but unlike their afflicted sister they were clinically well with no evidence of bone disease. How long the 3 siblings had had these biochemical disturbances and whether they might have developed clinically apparent disease with time remained unanswerable. The biochemical defects could conceivably be present from birth even in the adult cases but not clinically manifest unless the patient was confronted by environmental factors e.g. pregnancy and lactation which would place a strain on the impaired mechanism for calcium and phosphorus conservation. On the other hand adult cases have been reported in which a retrospective search for glycosuria on preceding urinalyses have yielded negative results [76]. Even in the infantile form Bickel has reported well-documented cases indicating that the abnormality in renal function was not manifest during the first few months after birth [77].

Dent has pointed out [45] that in the hereditary diseases generally which include some forms of aminoaciduria all the cells of the body carry the defective gene while only in the kidney in the syndrome does the abnormality resulting from the defective gene give rise to clinically recognizable disturbances. In this regard the association of cystine storage with the syndrome in some instances remains a confusing feature. Most workers accept the results of Dent [18] and of Levered [47] referred to above which indicate no elevation of plasma amino acid levels in the syndrome although Bickel claims that elevated plasma levels may be present [14-77]. If elevated plasma amino acid levels are not present some local factor which is not essential to the development of the syndrome must be responsible for the widespread deposition of cystine crystals seen in patients with cystinosis. DeToni's view [13] that cystinosis and the syndrome are different entities whose coexistence is the result of an acquired renal tubular lesion producing the syndrome as a complication of cystine storage may have merit. This view has also been stated by

of the *syndrome*. A tubular reabsorptive defect seems to be directly responsible for the aminoaciduria, glucosuria, phosphaturia, and the tendency to excrete an alkaline urine, and secondarily responsible for the systemic acidosis and skeletal changes. The anatomic changes found by Darmady and associates [59, 60] appear to provide a morphologic basis in the proximal tubule for such a defect. The proximal tubule is thought to be the site of reabsorption of glucose [43], and Fanconi [63] considers the proximal tubule to be the site of reabsorption of amino acids and phosphate as well. Hence the morphologic changes are to this extent consistent with the functional derangements.

When one asks the important next question, namely, what is the cause of the renal tubular defect, a unitarian approach to the *syndrome* is no longer tenable. The familial occurrence of this rare *syndrome* early suggested an hereditary basis for the disease. Recently, however, the renal defects associated with the *syndrome* have been recognized repeatedly under circumstances in which renal damage was clearly acquired. Harrison and Harrison [64] reported that injections of maleic acid into rats may produce renal glucosuria, phosphaturia, and a generalized aminoaciduria. It had previously been demonstrated that this compound interfered with the renal excretion of acid by acidotic dogs [65]. These renal disturbances proved reversible. Spencer and Iranglen [66] have reported gross glucosuria and aminoaciduria without elevated blood glucose or amino acid concentrations occurring transiently during the recovery phase of acute renal failure in a patient who suffered an extensive Lysoil burn. Experimental uranium poisoning may produce glucosuria and aminoaciduria [67-68]. Gross renal aminoaciduria has been observed in lead poisoning [69-71] and in cadmium, mercury, and uranium poisoning [72]. In at least one instance of lead poisoning in a child [70] the aminoaciduria was associated with glycosuria, persistent hypophosphatemia, and rickets. The acquired *syndrome* in this child resolved after treatment of the lead poisoning. Vitamin D deficiency has been associated with renal aminoaciduria [73]. Of considerable interest is the association of multiple myeloma and the adult form of the *syndrome* reported recently by Engle and Wallis [74] and noted earlier by Sirota and Hamerman [30]. These clinical and experimental observations indicate that the *syndrome* may have multiple etiologies in which the common denominator is renal tubular injury with impairment especially of the systems that are important in the renal tubular handling of amino acids, glucose, and phosphate.

The hereditary nature of this *syndrome* was first noted by Abderhalden [1] and has been referred to repeatedly since. Duplication of the *syndrome* in siblings and blood relationship between parents have been noted [10]. Dent and Harris [75] concluded from their study of the genetics of this *syndrome* that the simplest view is that we are concerned with a simple

*drome*) To this list should probably be added impaired tubular reabsorption of bicarbonate as seen in renal tubular acidosis [41] which frequently occurs in the *syndrome* as discussed above Dent [44] had earlier proposed a somewhat similar subdivision of possible conditions arising from combinations of separate tubular reabsorptive defects Thus it is clear that the *syndrome* constitutes no clear-cut entity with distinct clinical functional or etiologic boundaries but merges into the spectrum of disturbances arising from all possible renal tubular defects

## TREATMENT

The problem of management of a condition whose clinical features are the result of renal losses of certain body constituents would seem to be one primarily of replacement therapy The renal losses of glucose or of amino acids in this condition have not constituted a problem because they are quantitatively not sufficient to produce nutritional disturbances Acidosis and phosphate loss require treatment in order to heal the skeletal lesions The rickets and osteomalacia have repeatedly been found to be resistant to usual amounts of vitamin D but improvement in skeletal and biochemical disturbances occurs with large doses of vitamin D (50 000 to 400 000 I U daily) [21 38 39 44 82] It is of special interest that the aminoaciduria may be diminished although not necessarily restored to normal values by large doses of vitamin D [83]

In view of the excessive renal clearance of phosphate it would seem rational to supplement the dietary intake of phosphate and to replace the excessive loss Until the skeleton has remineralized supplementary calcium may also be needed but a high calcium intake together with large doses of vitamin D considerably increase the risk of hypercalcemia and should be undertaken only if frequent and careful follow up determinations of serum and urine calcium levels are possible

The acidosis has been treated successfully with the solution of Shohl [30 34] which contains 140 gm citric acid and 98 gm sodium citrate per liter Since potassium deficiency is commonly present potassium bicarbonate or citrate may be necessary However as chronic acidosis is presumably the cause of the potassium depletion once acidosis has been relieved no further excessive potassium losses should be incurred and supplementary potassium should not be continuously required

Combinations of the above replacement therapy have increased considerably the optimism with which immediate prognosis in this *syndrome* may be regarded Since therapy merely replaces losses rather than cures the tubular defect it is evident that therapy must be continued indefinitely Replacement therapy does not seem to prevent the slow progression of renal impairment with ultimate death from glomerular failure and uremia [8<sub>4</sub>] Since terminal renal failure may perhaps occur more

Harrison [78] No one has yet produced a satisfactory explanation of how a renal tubular defect resulting in loss of amino acids can simultaneously result in excessive deposition of cystine in the tissues. Clearly some factor in addition to the renal lesion must be present in these cases.

The findings of Salassa, Powers, Ulrich and Hayles [39], who carefully studied the effects of large doses of vitamin D (400 000 units daily) for a period of 30 days in two patients, deserve special mention. Not only did the balances of calcium and phosphorus improve markedly with a reduction in renal clearance of phosphate, but all other parameters that were studied likewise improved. Thus the aminoaciduria decreased, glucosuria diminished, serum bicarbonate concentrations rose to normal, and serum chloride levels fell to normal. The decrease in aminoaciduria occurred in the absence of a detectable change in the plasma concentration of amino acids. Curiously, the acidosis corrected itself in spite of a considerable decrease in urinary ammonium excretion. Presumably a more acid urine with a high titratable acid excretion must have resulted from the vitamin D, but in the one case where titratable acid excretion rates were reported, no increase was found. These interesting results require confirmation in a larger number of cases. The fact that vitamin D deficiency is associated with an aminoaciduria and that the aminoaciduria is corrected by administration of vitamin D [73] supports at least some of the findings of Salassa and associates. Perhaps some processes in the renal tubule which normally are dependent upon vitamin D are defective but in some cases at least are partially correctable by huge doses of vitamin D. Much more work will be required before knowledge of the normal tubular reabsorptive mechanisms and their relationship to the action of vitamin D will permit more than conjectures on the etiology of this condition.

The arbitrary status of this syndrome has been emphasized by recent reports in which all possible combinations of the glucosuria, phosphaturia and aminoaciduria have been observed. Thus Luder and Sheldon [79] reported "A Familial Tubular Absorption Defect of Glucose and Amino Acids" in which only glucose and amino acid reabsorption were impaired. This defect appeared to be the result of a dominant genetic characteristic. They considered this defect to be one of seven possible combinations of defects deriving from abnormalities of tubular reabsorption of phosphate, glucose and amino acids: (1) glucose alone (as in renal glucosuria); (2) phosphate alone (possibly vitamin D-resistant hypophosphatemic rickets [44]); (3) amino acids alone (cystinuria or hepatolenticular degeneration [80-81]); (4) glucose with phosphate (combination of renal glucosuria and hypophosphatemic rickets [44]); (5) phosphate and amino acids (aminoaciduria in vitamin D deficiency [73]); (6) glucose and amino acids [79]; (7) phosphate, glucose and amino acids (the syn-

readily in the potassium-deficient subject [62], any evidence of urinary tract infection should be carefully investigated and specifically treated.

In contrast to 'cystinuria, cystine excretion in the urine may be either normal or only moderately increased. Nephrolithiasis due to cystinuria in this *syndrome* has been reported so far on only one occasion [48] and no specific measures are ordinarily required for its prevention.

Those who claim cures for the *syndrome* must take cognizance of the acquired forms secondary to reversible renal tubular damage from a wide variety of agents.

## SUMMARY

1 A *syndrome* characterized by rickets or osteomalacia with renal glucosuria, aminoaciduria, phosphaturia and frequently acidosis has been reviewed. This *syndrome* may appear early in life (infantile form) or manifest itself first during later life (adult form).

■ The associated physiologic disturbances are best explained as consequences of a defective renal tubular reabsorption of glucose, amino acids, phosphate and bicarbonate.

3 A characteristic morphologic change has been described in the proximal tubule of these subjects which provides a plausible anatomic basis for the functional disturbances.

4 The clinical and experimental observations which have been reviewed indicate that the *syndrome* may have multiple etiologies in which the common denominator is injury to the proximal renal tubule with impairment of its normal reabsorptive functions. Thus acquired forms of the *syndrome* are now recognizable in addition to the genetically determined forms which were initially described and in which the hereditary factor acts like a simple recessive character.

5 Rational therapy aimed at replacing abnormal renal losses is outlined. Reversal of the morphologic changes in the kidney once they have developed seems unlikely and no way of halting the gradual development of glomerular failure and uremia is known at present.

reached levels several fold greater than the concentration in glomerular filtrate at  $T_m$ . The display in the glucose titration curve for the whole kidney as well as for the individual nephron could be explained on this basis.

The nature of the hypothetical cellular carrier if indeed one exists has not been elucidated. It has been postulated that the initial step in transport is phosphorylation of glucose mediated by hexokinase and adenosine triphosphate and subsequent dephosphorylation through the action of a phosphatase [16-17]. The glucose 6-phosphate formed in the first reaction is assumed not to diffuse out of the cell and the removal of free glucose by phosphorylation would then favor the inward movement of glucose in the direction of the concentration gradient. Hexokinase, non-specific alkaline phosphatase and the specific glucose 6-phosphatase are found in proximal tubular cells. However, the weight of evidence is heavily against a phosphorylated sugar as an intermediate in the transport process [10]. When phlorizin was administered to animals to produce almost complete block of glucose reabsorption, no inhibition of alkaline phosphatase in the proximal convoluted tubules, shown histochemically, could be found [18]. Phlorizin in doses which produced profound glycosuria did not alter the time curve of disappearance of injected  $P^{32}$ -labeled inorganic phosphate from the plasma of cats [19]. These data of Dratz and Handler [19] indicated that in the presence of phlorizin, normal or even accelerated synthesis of glucose esters is seen. The authors concluded that if a highly active fraction of either glucose 1-phosphate or glucose 6-phosphate mediates renal tubular transport of glucose, then this must be present in amounts too minute to be detected by their technique. In addition, there are two clinical observations which fail to support the unique role of either alkaline or glucose 6-phosphatase in the transport reactions. Cori noted the absence of glycosuria in patients with glycogen storage disease in whom the specific glucose 6-phosphatase was lacking [20]. Similarly, normal carbohydrate metabolism has been observed in subjects with hypophosphatasia in whom alkaline phosphatase activity is decreased or absent [21].

Additional evidence against the phosphorylation hypothesis has been obtained through studies of active transport of sugars in the small intestine, a situation analogous to that in the renal tubule. The experiments of Solis on the substrate specificity of intestinal hexokinase demonstrate clearly that this enzyme cannot directly participate in active transport [22]. He found that several hexoses actively transported by the intestine were not phosphorylated by intestinal homogenates. More directly, it has been shown that certain hexoses lacking a hydroxyl group at carbon atoms 1 or 2 can still be transported by intestinal sacs *in vitro* against a concentration gradient [23]. Further examination of the substrate specificity of this reaction has shown that these compounds are transported

transport of glucose. This subject has been recently reviewed by Taggart [10].

The application of micropuncture techniques has demonstrated in various Amphibia and mammals that glucose is present in the glomerular filtrate in the same concentration as in the plasma water [11, 12]. In the proximal convoluted tubule sugar is reabsorbed against an increasing concentration gradient, so that by the mid point of this tubule little glucose remains in the lumen. The reabsorptive process which is blocked by the glycoside phlorizin, is not restricted to any particular segment of the proximal tubule, but it is not demonstrable in the distal tubule. In the presence of phlorizin the concentration of reducing substance in the tubular urine may increase to as high as three times that of plasma as water is reabsorbed. In phlorizinized *Necturus*, glucose can diffuse back toward the plasma if the concentration in the tubular lumen is significantly greater than in plasma.

It has been shown in the dog by Shannon [13] and in man by Smith [14] that as the concentration of glucose in the blood is progressively increased the amount reabsorbed ( $T$ ) by the tubules approaches a maximum ( $T_m$ ). Shannon assumed that as the load of glucose presented to the tubules increases progressive saturation of the reabsorptive mechanism occurs until a maximum level is reached and the excess is excreted in the urine. He postulated that the sequence of reactions in glucose transfer involves (1) a reversible combination of the solute with a hypothetical cellular element present in constant but limiting amounts and (2) decomposition of this complex by a reaction which is first-order in type and rate limiting for the whole process.

Although Shannon's data fitted well with his hypothesis clearance data obtained in man show variable deviations, or splay, from the ideal curve [14]. The explanation has been offered that even in the normal kidney with loads less than the maximal average the transport in some individual nephrons will be less than in others [15]. Since the capacity of some tubules for reabsorption will be exceeded at relatively low levels glucose would be excreted from these nephrons before the average maximal load is reached. It has been further assumed that the titration curves for both kidneys would deviate from the "theoretical" in proportion to the degree of heterogeneity in the nephron population.

It has however been pointed out by Mudge [15] and Berlner [49] that the assumptions on which this explanation is based can be only an approximation, i.e., that each nephron excretes no glucose until completely saturated. There are no experimental data which conclusively prove this. On the contrary if Michaelis-Menten kinetics are applicable to the process of glucose transport across a tubule cell it is apparent that maximal rates would not be attained until concentration of the substrate

## NATURE OF THE TUBULAR ABNORMALITY IN RENAL GLYCOSURIA

It is not possible to localize the fundamental defect in renal glycosuria. With the exception of two cases published in 1935 and 1939 there is no recent report of pathologic anatomic findings in this disease. Marble [1] has pointed out that in the earlier publication of Grote and Heilmann [36] the patient probably had true diabetes mellitus. The other case reported by Monasterio [37] was evidently one of true renal glycosuria with a similar disease in a sibling and diabetes mellitus in one parent. Histologic examination of a biopsy specimen of one kidney showed in many places marked flattening of tubular epithelium; this was occasionally so striking that the epithelium resembled endothelium. The author was careful to note that the relationship of this change to the functional abnormality was not certain.

There have been several studies of patients with renal glycosuria using clearance techniques [38-42]. The glomerular filtration rate [38-40], secretion of  $\beta$  aminohippuric acid [38], reabsorption of phosphate [43] and amino acids [15] have been reported normal in these patients. There is no evidence of generalized progressive renal failure.

Data on glucose reabsorption as reported by several groups of investigators are summarized in Table 38-1. It was originally proposed by Reubi [38] and Bradley [40] that the patients seemed to fall within two separate groups: those with normal glucose  $T_m$  and those with low glucose  $T_m$ . Reubi concluded that in those patients with low glucose  $T_m$  a familial tendency was evident. Bradley thought the reverse was true. Taggart [44] in reviewing the available literature including the data collected by Bradley, Reubi, and Lambert, concluded that the cases did not appear to fall into two distinct categories according to the glucose  $T_m$ , but were evenly distributed from the lowest to the highest values. This is evident as shown in Table 38-1.

Data obtained with the titration method of Smith [14] are of considerable interest. Use of this technique in the patients with low glucose  $T_m$  has led to the conclusion that the defect in glucose reabsorption is diffuse involving most if not all nephrons. In the other individuals with renal glycosuria in whom the glucose  $T_m$  was within the normal range both Reubi and Bradley commented upon the exaggerated splay in the titration curves. They attributed this to a heterogeneity among nephrons whether on a functional or anatomic basis. Reubi further suggested that in these individuals there were actually two distinct groups of nephrons. However, as previously mentioned, configuration of the titration curve may be a function of the kinetics of the tubular transfer reactions rather than an expression of heterogeneity among nephrons. For example, a

which possess a  $\beta$  pyranose ring, a methyl or substituted methyl group at carbon 5 of this structure, and a hydroxyl group in the glucose configuration at carbon 2 [24] a structural specificity differing distinctly from that of mammalian hexokinase [25] Reactions which involve removal or transfer of oxygen at carbon 2 of the sugar molecule or which require the presence of carbon bound hydrogen at the same position have further been excluded [26] In the kidney it has also been shown by Chinard who infused glucose  $1\text{ C}^{14}$  into the renal artery of anesthetized dogs, that the sugar is transported without breakdown and resynthesis of the six carbon chain [27]

Some comment concerning the inhibitory effect on renal sugar transport of the glycoside phlorizin is pertinent since many of the hypotheses discussed above assume that the action of this compound is highly specific Phlorizin has been shown to inhibit several nucleotide requiring enzymes such as phosphorylase [28] Ehrlich ascites tumor hexokinase [29] mutarotase [30], and aerobic phosphorylation in homogenates of guinea pig kidney cortex [30] In addition, it inhibits the entrance of sugars into erythrocytes [31] and Ehrlich ascites tumor cells [32] which do not possess a mechanism for the accumulation of these substances against a concentration gradient It has recently been shown that slices of rabbit and rat kidney cortex can accumulate  $\beta$  galactose  $1\text{ C}^{14}$  a sugar reabsorbed by mammalian kidney tubules, against an apparent concentration gradient [33] In the absence of oxygen or in the presence of dinitro-ortho cresol (an inhibitor of oxidative phosphorylation) the amount of galactose entering the cells is limited to that expected from diffusion equilibrium The extent of accumulation in a given time period is a function of the external galactose concentration and shows a maximal rate Glucose competitively inhibits this accumulation Phlorizin in concentrations previously shown to be active *in vivo* inhibits the entrance of galactose into the tissue not only under conditions where accumulation can occur but also when accumulation has been inhibited by dinitro ortho cresol In the light of the results obtained with this *in vitro* model other experiments which minimize the role of diffusion of glucose from the tubular lumen in the presence of phlorizin must be reevaluated Diffusion becomes evident only when the process of active transport is blocked [34]

In summary glucose is present in the glomerular filtrate in concentration equal to that in the plasma water It is reabsorbed in the proximal convoluted tubules against an ever increasing concentration gradient Reabsorption of the sugar is mediated by energy requiring processes has a restricted specificity and is susceptible to inhibition by phlorizin, which in some manner restricts penetration of sugar into the cell A maximal rate of transport is observed both *in vitro* and *in vivo* The nature of the transport mechanism remains obscure and to date no chemical reaction involving the transported sugar has been demonstrated

of the tubular membrane towards the diffusion of glucose could also result in a change in the shape of the titration curve in the same direction.

One can therefore only speculate concerning the tubular abnormality in renal glycosuria. It is possible that no one explanation will suffice to account for the mechanism of the defect in all cases.

## GENETICS

The abnormality in renal glycosuria is probably inherited as a Mendelian dominant characteristic [2 7 8]. Further examination of members of affected families using more refined techniques of examination (such as Smith's titration method [9]) is indicated before this can be established with certainty.

The most complete study of the heredity of renal glycosuria was published in 1927 [47]. Hjarne was able to obtain information on 141 out of 199 individuals in three generations who had common ancestors in the eighteenth century. Glycosuria with normal blood sugar levels was found in 18 on unlimited carbohydrate intake and an additional 6 persons had glycosuria during the course of a glucose tolerance test only. Hjarne concluded that the defect was inherited as a dominant characteristic in view of the following:

- 1 Glycosuria occurred in male as well as female members of the family.
- 2 Where neither parent had glycosuria none of the offspring had the abnormality.
- 3 Where either of the parents had glycosuria some of the children generally had it.

Although true diabetes mellitus was present in 7 members of the family studied by Hjarne, the mode of inheritance of this defect was not similar to that of renal glycosuria. Similar conclusions regarding inheritance of renal glycosuria were reached by Schnell [7] and supported by the report of Brown and Poleshuck [48]. So far the heterozygote has not been differentiated from the homozygote—although I roesch et al [46] have suggested from the evaluation of titration curves in three brothers with the defect the possibility that the defect may be expressed in the heterozygote but more distinctly in the homozygote.

## SUMMARY

1 Renal glycosuria is an abnormality in which glucose is excreted in the urine at normal concentrations of blood glucose. The condition probably inherited as a Mendelian dominant trait is a benign one unassociated with any clinical abnormality.

2 It is still not certain whether several different abnormalities are included under the name *renal glycosuria*. Separate entities could depend

Values corrected to 1.73 m<sup>2</sup> body surface

† Values in late pregnancy

‡ Values 6 months following delivery In this case studied early in pregnancy no glucose  $T_m$  was observed with plasma glucose concentrations of 888 mg/100 ml  $T$  glucose was 810 mg/min

decrease in the affinity of the substrate (glucose) for the transfer system could result in a shift of the curve to the right without altering  $T_m$ .<sup>1</sup> Thus the point at which the ratio  $T/T_m$  reaches 0.5 would occur at higher plasma concentrations of glucose. Changes in the permeability characteristics

<sup>1</sup> The amount of glucose reabsorbed per minute ( $T$ ) is calculated by subtracting the amount appearing in the urine per minute from the filtered load (plasma concentration  $\times$  glomerular filtration rate in milliliters per minute). It is apparent that  $T$  glucose represents a mean rate of tubular reabsorption since the amount reabsorbed decreases progressively along the proximal convoluted tubule. Until the maximal rate of reabsorption ( $T_m$ ) is reached, it is usually considered that  $T$  is a function of load. However, since the glomerular filtration rate does not significantly change in any one study as plasma glucose concentration is increased, then  $T$  may be considered a function of plasma glucose concentration. Although  $T$  does not represent true initial velocity for the reabsorption process, if the system follows Michaelis-Menten kinetics, then an approximate apparent  $K_m$  would be the concentration of plasma glucose when  $T/T_m = 0.5$  ( $1/V_{max} = 0.5$ ). This problem has been discussed by Walbrant [45].

upon a reduction of renal threshold on the one hand or upon a decrease in the maximal capacity of the renal tubule to reabsorb glucose on the other

3 The majority of cases studied show a decrease in  $T_m$  glucose and a variable degree of 'splay' of the titration curve. It remains to be determined whether the abnormality is diffuse in all cases or the result of a heterogeneous population of nephrons in some cases

4 The fundamental mechanism of the renal tubular transport of glucose remains obscure, until more is known about this process the abnormality in renal glycosuria cannot be further defined

detailed here. Many attempts have been made to define the nature of the underlying tubular defect and the resulting pathogenesis of the changes in blood and urine. From these studies has come general agreement on the clinical features and the over all pathogenesis of the disorder, but a more precise definition of the disease at the cellular or enzymatic level remains to be obtained. It is the purpose of this chapter to review current concepts of the nature of the tubular disorder in renal tubular acidosis and to discuss how this disorder may relate to the clinical manifestations of the disease.

## CLINICAL AND PATHOLOGIC MANIFESTATIONS

Since the major attention of this chapter is to be directed toward pathogenesis, the clinical syndrome of renal tubular acidosis will be only briefly summarized. Excellent descriptions of typical case histories are available elsewhere [8-10]. In general the syndrome has been described in two groups of patients—in infancy or in older children and adults. In infancy the clinical picture is quite non-specific and is often described under the all inclusive term "failure to thrive." There may be anorexia, nausea, vomiting, polyuria, dehydration, hypercalcemia, and fever. Nephrocalcinosis visible to x-ray examination is rare. If the patient is treated adequately, the ultimate prognosis is excellent. There is complete remission in the majority of cases [11]. This syndrome in infancy has not been so well studied as in the adult. It is not entirely clear that these two groups of patients have the same disorder.

In older children and adults, the constant acidosis (retention of  $H^+$ ) may be associated with non-specific complaints of anorexia, lethargy, fatigue, and failure of normal growth. The most serious complications relate to the loss of cations from the body, especially calcium and potassium. Depletion of calcium may be associated with rickets in childhood or osteomalacia in adults [9]. During the excessive urinary loss of calcium, local renal complications such as nephrocalcinosis and nephrolithiasis frequently occur. The excessive urinary loss of potassium may lead to recurrent attacks of weakness or even flaccid paralysis. The patient may have polyuria with impairment of urine concentration. The extracellular fluid pattern is that of a metabolic acidosis associated with hyperchloremia. In addition, studies may reveal hypokalemia or the chemical pattern in the serum of rickets or osteomalacia, i.e., low normal to low calcium, low phosphorus, and high alkaline phosphatase concentrations. In Fig. 39-1 is summarized the incidence of certain of the clinical features of renal tubular acidosis as found in 28 patients [7-10, 12-19]. The average age at the time of diagnosis in this series was 29, although symptoms often preceded diagnosis by a number of years. Patients are listed as having  $H^+$  depletion only if there were symptoms which

## Chapter 39

### Renal Tubular Acidosis

---

*Lloyd H. Smith Jr*

Renal tubular acidosis is a descriptive term for a rare sometimes familial disorder of the renal tubule characterized by an inability to excrete a urine of normal acidity. This primary defect leads to a continuing hyperchloremic acidosis which is often associated with one or more secondary complications such as hypercalciuria with nephrolithiasis and nephrocalcinosis, rickets or osteomalacia, and severe potassium depletion.

Most of the disorders of renal tubular function which have been described as single entities are occasionally found as components of multiple tubular defects. This is true for renal tubular acidosis which may be one of the spectrum of abnormalities of the Fanconi syndrome [1] (cf Chap. 37). The syndrome of renal tubular acidosis may be closely simulated by the chronic administration of potent carbonic anhydrase inhibitors, a fact of considerable theoretical importance in speculations about its pathogenesis. Finally the extracellular fluid pattern of chronic hyperchloremic acidosis may be found following bilateral ureterosigmoid transplantations [2] or during the continued ingestion of large amounts of ammonium chloride. A similar pattern has been described in a group of patients with chronic pyelonephritis [3].

First descriptions of renal tubular acidosis were those of Lightwood in 1930 [4] and of Butler, Wilson and Earber in 1936 [5]. The syndrome was subsequently studied extensively by Albright and his collaborators with clarification of the major features of the overall physiologic defect in renal function [6]. From these studies plausible explanations for most of the systemic complications were offered and a rational therapeutic regimen was proposed. Over the last two decades the disorder of renal tubular acidosis has been recognized with increasing frequency and described under at least 14 separate terminologies [7] which will not be

tion reactions in intermediary metabolism. From a quantitative standpoint the lung with its feed back control adjustment for excreting this volatile anhydride of carbonic acid is the organ par excellence of acid base balance in that it can excrete a hundredfold more acid than the kidney and is capable of minute by minute adjustment of body pH. A second normal stress on the maintenance of pH is the metabolic liberation of certain acidifying anions of dietary origin particularly phosphate and sulfate. On an average dietary intake these represent approximately 50 to 100 mEq excess acid per day. It is in the controlled excretion of this fixed acid load that the kidney primarily serves to rid the body of excess hydrogen ions. The mechanisms by which the kidney serves this function can be arbitrarily divided into several categories. It will be apparent that these are in fact closely related phenomena: (1) excretion of sulfate and phosphate; (2) conservation of filtered bicarbonate; (3) tubular secretion of hydrogen ion; (4) tubular synthesis and excretion of ammonia.

#### *Excretion of Sulfate and Phosphate*

From many clearance studies it has been established that phosphate and sulfate are filtered by the glomerulus and partially reabsorbed by the tubule. Retention of the anions sufficient to produce acidosis is invariably associated with marked reduction of glomerular filtration. This is the type of renal acidosis found in most patients with uremia. If the retention of these anions were completely balanced by a corresponding retention of cations (largely the sodium ion) no acidosis would result. In the cross purpose of maintaining the constancy of intracellular and extracellular osmolarity this general increase of cation concentration is not allowable. These anions therefore displace the anions of weaker acids especially bicarbonate. Unless there is a corresponding reduction of carbonic acid mediated by the respiratory center and lung, acidosis is the inevitable result.

#### *Conservation of Filtered Bicarbonate*

The kidney is primarily concerned with the conservation of the corresponding buffer base (largely sodium) rather than the bicarbonate ion per se which is almost limitlessly available from metabolic carbon dioxide. It is evident that the maintenance of acid base balance is endangered by the profligacy of a glomerular filtration of approximately 45 moles bicarbonate per day, approximately fifteen times that normally present.

\* In the discussion to follow the terms acid and base are employed in the conventional clinical usage which is incorrect as chemical terminology [2, 3]. The terms imply the physiologic effects of certain anions and cations rather than their properties as proton donors or acceptors. Switching to more correct usage here would probably result in loss of clarity.

seemed clearly related to potassium loss. Other patients exhibited varying degrees of hypokalemia.

The few autopsy studies of the kidney in renal tubular acidosis have failed to reveal a constant pathologic picture. In general the glomeruli have been uninvolved. Interstitial calcification, evidence of pyelonephritis and vacuolization of tubular cells have been reported [6]. No abnormality comparable to the "swan neck" deformity of the tubule in the Fanconi syndrome has been described [20]. The tubular changes may be in part attributable to chronic potassium depletion [21].

Fig. 39-1 The incidence of certain of the clinical features of renal tubular acidosis as found in 28 patients from the literature [10, 12, 15].

## PATHOGENESIS

Renal tubular acidosis is associated with a deficient acidification of the urine despite a continuing systemic acidosis. When the acidification mechanism is placed under additional stress by the use of acid or acid-forming salts, there is little or no further decrease in urine pH. Response of the kidney to systemic acidosis is therefore maximal but inadequate. Clearly the logical point of departure in investigating this syndrome has been the normal regulatory role of the kidney in acid-base balance in an attempt to determine in what manner this normal pattern is deranged.

### ROLE OF THE KIDNEY IN ACID-BASE BALANCE ✓

To attempt a general review of acid-base balance would be presumptuous in the present context. The following summary will relate only to the mechanisms by which the kidney contributes to the physiologic control of the hydrogen ion over the tenfold range compatible with life.

In man there is normally a constant tendency toward acidosis largely because of the liberation of carbon dioxide by certain specific decarboxyla-

tion reactions in intermediary metabolism. From a quantitative standpoint the lung with its feed back control adjustment for excreting this volatile anhydride of carbonic acid is the organ par excellence of acid base balance in that it can excrete a hundredfold more acid than the kidney and is capable of minute by minute adjustment of body pH. A second normal stress on the maintenance of pH is the metabolic liberation of certain acidifying anions of dietary origin particularly phosphate and sulfate. On an average dietary intake these represent approximately 50 to 100 mEq excess acid per day. It is in the controlled excretion of this fixed acid<sup>1</sup> load that the kidney primarily serves to rid the body of excess hydrogen ions. The mechanisms by which the kidney serves this function can be arbitrarily divided into several categories. It will be apparent that these are in fact closely related phenomena: (1) excretion of sulfate and phosphate (2) conservation of filtered bicarbonate (3) tubular secretion of hydrogen ions (4) tubular synthesis and excretion of ammonia.

#### *Excretion of Sulfate and Phosphate*

From many clearance studies it has been established that phosphate and sulfate are filtered by the glomerulus and partially reabsorbed by the tubule. Retention of these anions sufficient to produce acidosis is invariably associated with marked reduction of glomerular filtration. This is the type of renal acidosis found in most patients with uremia. If the retention of these anions were completely balanced by a corresponding retention of cations (largely the sodium ion) no acidosis would result. In the gross purpose of maintaining the constancy of intracellular and extracellular osmolarity this general increase of cation concentration is not allowable. These anions therefore displace the anions of weaker acids especially bicarbonate. Unless there is a corresponding reduction of carbonic acid mediated by the respiratory center and lung acidosis is the inevitable result.

#### *Conservation of Filtered Bicarbonate*

The kidney is primarily concerned with the conservation of the corresponding buffer base (largely sodium) rather than the bicarbonate ion per se which is almost limitlessly available from metabolic carbon dioxide. It is evident that the maintenance of acid base balance is endangered by the profligacy of a glomerular filtration of approximately 4.5 moles bicarbonate per day approximately fifteen times that normally present.

<sup>1</sup> In the discussion to follow the terms *acid* and *base* are employed in the conventional clinical usage which is incorrect as chemical terminology [22-23]. The terms imply the physiologic effects of cations and anions respectively rather than their properties as proton donors or acceptors. Switching to more correct usage here would probably result in loss of clarity.

in the entire extracellular fluid. This must be largely reabsorbed by tubular action. Evidence from several sources has indicated that glomerular filtrate is reabsorbed in the proximal segment of the tubule with little change in ionic concentration or pH [24]. It follows that five sixths of bicarbonate must be similarly reabsorbed here. It should be noted that some acidification has recently been demonstrated by micropuncture in the proximal tubule of the rat [25]. Acidification of the urine which occurs in the distal tubular segment, is associated with the reabsorption of most of the remaining bicarbonate in proportion to the final hydrogen ion concentration attained. It was previously postulated that the reabsorption of bicarbonate by these two segments occurred through different mechanisms—proximal reabsorption representing an active transport mechanism, distal reabsorption resulting from an ion-exchange reaction of  $H^+$  for  $Na^+$  with back diffusion of the released carbon dioxide [26]. Recently the use of more powerful carbonic anhydrase inhibitors has indicated that the reabsorption of bicarbonate is related to ion exchange at both sites [27], the essential difference lying in the ability of the distal tubular cell to concentrate  $H^+$  against a positive gradient. The reabsorption of bicarbonate is therefore intimately connected with the tubular secretion of  $H^+$ , which will be discussed below. Barring marked shifts in urine  $P_{CO_2}$ , the urine bicarbonate is a direct function of urine pH as signified by the Henderson Hasselbalch equation. "Bicarbonate wasting" therefore is roughly synonymous with defective acidification of the urine, as seen in renal tubular acidosis and in some patients with the more usual forms of chronic nephritis [28].

### *Tubular Secretion of Hydrogen Ions*

Hydrogen ion is concentrated in urine in excess of that found in plasma with the usual acid ash diet, and the concentration rises still further to compensate for systemic acidosis. This simple fact has long been known. The mechanism by which this is effected and controlled is still under investigation. Considerable information has been obtained by imaginative use of classical clearance techniques. Hydrogen ion secretion is part of the general phenomenon of ion exchange across cell membranes, an area of investigation which is just beginning to be approached in vitro.

For some time the assumption was made that acidification of the urine is effected by the selective tubular reabsorption of the more basic members of filtered buffer pairs—i.e.,  $Na_2HPO_4$  in preference to  $NaH_2PO_4$ . Hydrogen ions would therefore be progressively concentrated intraluminally. It was implicit in this theory that all  $H^+$  appearing in the urine has traversed the glomerular membrane. This conception of urine acidification was clearly demonstrated to be untenable in the classical studies of Pitts and Alexander [29]. Under their experimental conditions of acidosis and buffer infusions in dogs, it was shown that  $H^+$  appeared in

the urine (largely coupled with buffer as titratable acidity) in amounts considerably in excess of that which could be accounted for by glomerular filtration. The suggestion was made that the tubular cells secrete  $H^+$  into the lumen in exchange for  $Na^+$ . This exchange would allow a net loss of protons and simultaneously retrieve buffer base from the tubular urine. The source of  $H^+$  for this exchange was thought to be  $H_2CO_3$  produced by the hydration of carbon dioxide and catalyzed by carbonic anhydrase. The evidence in favor of such a pivotal function of carbonic anhydrase in urine acidification is indirect but impressive: a source of  $H^+$  within the renal tubular cells must be constantly available and capable of producing large amounts of exchangeable  $H^+$  (approximately 3 to 4 mEq  $H^+$  per min). Carbon dioxide as the major acid metabolically produced in the body would meet this requirement. Carbonic anhydrase is present in kidney cortex in high activity [30]. Finally a variety of chemicals known to inhibit carbonic anhydrase in vitro (notably sulfanilamide and more recently acetazolamide) interfere quickly and specifically with the renal acidification mechanism. No effects on other tubular functions have been detected [31].

The mechanism which controls the cationic exchange of  $H^+$  for  $Na^+$  across the cell membrane is not clear. The exchange in the proximal tubular segment is to be contrasted with that found in the distal segment as to both major function served and concentration gradient of  $H^+$  obtained. As previously pointed out the proximal exchange mechanism seems to be primarily designed to retrieve buffer base in the form of bicarbonate—perhaps four fifths or five sixths of that filtered being reabsorbed in this way. Micropuncture studies indicate that there is no change in pH in the proximal tubule, i.e. no net concentration of  $H^+$  [32]. Pitts has discussed the theory that the primary event is an active tubular reabsorption of  $Na^+$  in excess of  $Cl^-$  creating the observed negative intraluminal potential [33]. Hydrogen ions derived from carbonic acid would then simply diffuse into the lumen along an electrical gradient. Since there is no net concentration of  $H^+$  there is no associated diffusion of ammonia. This presumed diffusion of  $H^+$  seems to have no relationship to potassium secretion into the lumen. If in fact proximal reabsorption of bicarbonate is wholly dependent on  $H^+ Na^+$  exchange an impressive total of 20 to 30 mEq  $H^+$  per min must be produced and transferred by the proximal tubule.

The hydrogen ion-exchange mechanism in the distal tubular segment seems also to depend on the activity of carbonic anhydrase. In other respects it differs markedly from the simple diffusion thought to occur in the proximal segment. When maximally stimulated there is a concentration gradient of  $H^+$  of about eight hundredfold across the tubule (pH 4.6 in urine 7.4 in peritubular fluid). Although the exchange allows the salvage of the final one fifth or one sixth of bicarbonate buffer base

it also exchanges with the buffer bases of other filtered buffers, especially phosphate titrating them to a more acidic form. Finally the increased intraluminal  $H^+$  concentration appears to be a major factor leading to the diffusion of ammonia into the tubular urine. This will be discussed in more detail below. The nature of the active transport mechanism which can produce an eight hundred fold gradient of  $H^+$  across the inner cell membrane of the distal tubule has not been elucidated. Physiologic studies have firmly established, however, that the secretion of potassium into the distal tubular urine in exchange for sodium is competitively associated with the  $H^+$  transport mechanism; increased  $K^+$  secretion is produced by decreased  $H^+$  secretion and vice versa [27]. The limiting factor in  $H^+$  exchange in the distal tubule is that of a maximal concentration gradient (pH). When phosphate is infused during experimental acidosis and appears in the distal tubule to buffer the secreted  $H^+$  and thus to prevent the maximal pH gradient from being reached, the rate of  $H^+$  secretion increases markedly [29]. The maximal rate of  $H^+$  secretion by this mechanism has not yet been determined.

The fate of  $H^+$  secreted or diffusing into the tubular lumen depends wholly on the composition of the tubular urine at that point. The major products formed are  $H_2O$  from the decomposition of carbonic acid, the more acidic of buffer anionic pairs (especially  $H_2PO_4^-$ ), and the ammonium ion from the capture of  $H^+$  by diffused  $NH_3$ .

### *Tubular Synthesis and Secretion of Ammonia*

The central problem which the kidney faces in acid base balance is that of preserving buffer base endangered by glomerular filtration. Buffer base is represented by metabolic cations ( $Na^+$ ,  $K^+$ ,  $Mg^{++}$ ,  $Ca^{++}$ ) ingested as such and therefore of limited availability. The hydrogen ion is a cation which is metabolically produced and is therefore available for exchange reactions in the kidney to preserve buffer base as described above. Unfortunately  $H^+$  exchange is limited by the attending fall in pH. Ammonium is a second metabolically derived base which in effect serves to enhance the  $H^+$  exchange mechanism by neutralizing intraluminal  $H^+$ . The gradient is thereby maintained at less than the eight hundred fold maximum and  $H^+$  secretion can continue.

The source of urinary ammonia was clearly shown to be the amide group of glutamine and to a lesser extent the amino groups of other amino acids in classical studies by Van Slyke and his colleagues [34]. This has been widely confirmed. Data from many sources have indicated that three factors determine the amount of ammonia found in the urine: the availability of ammonia precursors, the cellular levels of enzymatic activities productive of  $NH_3$ , and the pH of the urine [35]. The influence of ammonia precursors is indicated by the increase of urinary ammonia found during the experimental infusion of glutamine or of a number of

other amino acids [36-37]. This presumably reflects a rise of intracellular ammonia concentration produced by increased substrate availability at a given enzyme concentration. Changes in substrate availability have not been shown to be of significance under other than experimental conditions. With continued acidosis there is a rise in urinary ammonia at a given pH. In the past this rise has been assumed to be due to an adaptive

Fig. 33-2 Diagram to illustrate the function of the renal tubule in regulation of acid-base balance.

increase of enzymatic activity within the distal tubular cell. Such an adaptive increase of glutaminase in the presence of experimental acidosis has been directly demonstrated in the rat [38]. Recent studies in the dog, however, have failed to demonstrate any adaptive increase of the enzymes known to be associated with ammonia production [39]. Indirect evidence from the stimulatory effect of various ammonia precursors during chronic ammonium chloride ingestion in man suggests enzymatic adaptation [37]. The mechanism by which this isohydric increase of ammonia production is brought about in man remains uncertain.

Urinary ammonia is generally found to be inversely proportional to

urine pH, at any particular stage of adaptation to acidosis. Evidence has been presented that ammonia, formed within the cell, passes into the tubule by free diffusion down a concentration gradient [35]. This is but one example of the nonionic diffusion of weak bases and acids across the renal tubule [40]. In alkaline urine equilibrium is attained so that the amount of ammonia passing into the urine is limited. In an acid urine ammonium ion is formed. The removal of free ammonia permits diffusion to continue. Seemingly the intraluminal reaction of  $H^+$  and  $NH_3$  serves to further the excretion of each by maintaining the necessary concentration gradient for ion exchange and free diffusion respectively.

This review of the role of the kidney in acid base balance has of necessity been abbreviated and overly didactic. Figure 39.2 summarizes diagrammatically many points in the above discussion. In summary the kidney must rid the body of the nonvolatile anionic residues of metabolism with the minimal expenditure of buffer base. This is carried out by the substitution within the tubular lumen of metabolically derived cations ( $H^+$  and  $NH_4^+$ ) for the buffer base which has been placed in jeopardy by glomerular filtration.

#### NATURE OF THE PRIMARY DEFECT IN RENAL TUBULAR ACIDOSIS

Renal tubular acidosis is the result of failure of the normal renal mechanisms for the defense of acid base balance. Glomerular filtration remains unimpaired unless secondary complications of nephrocalcinosis, nephrolithiasis and pyelonephritis lead to renal parenchymal damage. The

'fixed acids' (sulfate and phosphate principally) do not accumulate in extracellular fluid. They are normally excreted—but at an increased cost in buffer base. Despite a continuous systemic acidosis and in the face of an administered acid load there is bicarbonate wasting and inability to secrete  $H^+$  and  $NH_3$  into the tubular urine. In brief the glomerular component of renal acid base defense is normal; the tubular component is defective.

In the previous section evidence was presented that bicarbonate reabsorption proximal or distal is intimately related to the hydrogen ion-exchange mechanism for sodium. In general in renal tubular acidosis there is a normal direct relationship of urine bicarbonate and urine pH, there being no consistent alteration of urine  $P_{CO_2}$ . These facts being so, bicarbonate wasting seems not to be a primary defect but merely a reflection of an inadequacy of the tubular secretion of  $H^+$ .

The most consistent abnormality found in renal tubular acidosis is an inability to excrete urine of sufficient acidity in the face of systemic acidosis. Stated more precisely, the renal tubule does not exchange sufficient  $H^+$  to retrieve the necessary amount of buffer base. This is reflected in a decreased urinary titratable acidity. Normally minimal urine pH is about 4.5; in renal tubular acidosis it is usually found to be

60 to 68 From previous considerations of the  $H^+$  secretion mechanism several hypotheses concerning the defective acidification could be advanced (1) the tubule is unable to produce and secrete  $H^+$  sufficiently rapidly for normal function of the exchange mechanism (2) the tubule is unable to attain the usual maximal trans-tubular gradient of  $H^+$  of 800:1 (3) there is a failure of the proximal  $H^+$ -exchange mechanism which would result in diminished proximal bicarbonate reabsorption and consequent flooding of a normally functioning distal  $H^+$  secreting mechanism The three hypotheses will be considered here briefly

Studies of the response of the kidney to intravenous phosphate infusions have been carried out by several groups of investigators This procedure which increases the available urinary buffer (i.e. acceptor anion for  $H^+$ ) has regularly resulted in a marked increase of  $H^+$  secretion by the tubule in renal tubular acidosis usually with some decrease in urine pH [41 42 13] Rates of  $H^+$  secretion are produced which if sustained would easily correct the systemic acidosis These studies suggest that the kidney in renal tubular acidosis is quite capable of forming and secreting  $H^+$  at a rate commensurate with the amount of buffer base to be reabsorbed if this exchange can occur at a reduced  $H^+$  concentration gradient On the other hand the defective tubule cannot continue to secrete  $H^+$  in the face of a trans-tubular gradient of greater than approximately 80:1 rather than the normal maximal gradient of 800:1 In oversimplified terminology the defect in renal tubular acidosis seems to be primarily one of concentration rather than production or transport of  $H^+$

The hypothesis was advanced by Latner and Burnard [41] on the basis of studies of renal tubular acidosis in children that the defect lies in the proximal reabsorption of bicarbonate and that this obscures by neutralization a normally functioning distal acidifying mechanism This hypothesis was based largely on the following two observations (1) the infusion of neutral phosphate buffer led to a marked increase of  $H^+$  secretion with a considerable fall in urine pH (2) urine  $P_{CO_2}$ 's were found to be elevated in renal tubular acidosis and were considered to reflect the excessive formation of carbonic acid from  $HCO_3^-$  and  $H^+$  in the distal tubule It was suggested that in some way phosphate increased the proximal reabsorption of bicarbonate and thereby unmasked a more normally functioning distal  $H^+$  secretion mechanism The hypothesis of Latner and Burnard can be challenged The infusion of phosphate buffer at pH 7.4 regularly results in a fall of urine pH in normal subjects The explanation of this phenomenon has remained obscure [43] Urine  $P_{CO_2}$ 's have not been uniformly elevated in determinations on adult patients Finally if the proximal reabsorption of bicarbonate were the only tubular defect the infusion of bicarbonate in such patients should further tax the incompetent reabsorptive mechanism and result in an exacerbation of bicarbonate wasting This experiment has been carried out It was found that

urine pH, at any particular stage of adaptation to acidosis. Evidence has been presented that ammonia formed within the cell, passes into the tubule by free diffusion down a concentration gradient [30]. This is but one example of the nonionic diffusion of weak bases and acids across the renal tubule [40]. In alkaline urine equilibrium is attained so that the amount of ammonia passing into the urine is limited. In an acid urine ammonium ion is formed. The removal of free ammonia permits diffusion to continue. Seemingly the intraluminal reaction of  $H^+$  and  $NH_3$  serves to further the excretion of each by maintaining the necessary concentration gradient for ion exchange and free diffusion respectively.

This review of the role of the kidney in acid base balance has of necessity been abbreviated and overly didactic. Figure 39 summarizes diagrammatically many points in the above discussion. In summary, the kidney must rid the body of the nonvolatile anionic residues of metabolism with the minimal expenditure of buffer base. This is carried out by the substitution within the tubular lumen of metabolically derived cations ( $H^+$  and  $NH_4^+$ ) for the buffer base which has been placed in jeopardy by glomerular filtration.

#### NATURE OF THE PRIMARY DEFECT IN RENAL TUBULAR ACIDOSIS

Renal tubular acidosis is the result of failure of the normal renal mechanisms for the defense of acid base balance. Glomerular filtration remains unimpaired unless secondary complications of nephrocalcinosis, nephrolithiasis and pyelonephritis lead to renal parenchymal damage. The 'fixed acids' (sulfate and phosphate principally) do not accumulate in extracellular fluid. They are normally excreted—but at an increased cost in buffer base. Despite a continuous systemic acidosis and in the face of an administered acid load there is bicarbonate wasting and inability to secrete  $H^+$  and  $NH_3$  into the tubular urine. In brief the glomerular component of renal acid base defense is normal; the tubular component is defective.

In the previous section evidence was presented that bicarbonate reabsorption, proximal or distal, is intimately related to the hydrogen ion-exchange mechanism for sodium. In general in renal tubular acidosis there is a normal direct relationship of urine bicarbonate and urine pH, there being no consistent alteration of urine  $P_{CO_2}$ . These facts being so, bicarbonate wasting seems not to be a primary defect but merely a reflection of an inadequacy of the tubular secretion of  $H^+$ .

The most consistent abnormality found in renal tubular acidosis is an inability to excrete urine of sufficient acidity in the face of systemic acidosis. Stated more precisely, the renal tubule does not exchange sufficient  $H^+$  to retrieve the necessary amount of buffer base. This is reflected in a decreased urinary titratable acidity. Normally minimal urine pH is about 4.5; in renal tubular acidosis it is usually found to be

temic hyperchloremic acidosis. Because of this fact it has been speculated that renal tubular acidosis represents a tubular deficiency of carbonic anhydrase perhaps on a genetic basis. There is no direct evidence to support this hypothesis; its chief attraction is that of analogy. Two experimental findings moreover provide evidence against it.

Carbonic anhydrase is a metalloprotein enzyme the only known function of which is to accelerate the attainment of equilibrium of the reaction

It does not affect the equilibrium concentration of carbonic acid (and hence of its dissociation product  $\text{H}^+$ ) but only the rate at which this equilibrium concentration is reached. Previously cited evidence from phosphate infusions demonstrates that the rate of secretion of  $\text{H}^+$  by the tubule in renal tubular acidosis is adequate given an acceptor anion to allow this secretion to continue without an adverse shift in the  $\text{H}^+$  gradient. This implies that the rate of  $\text{H}^+$  production within the cell (presumably under the influence of carbonic anhydrase) is not a limiting factor in the acidification of the urine. It is difficult to visualize how carbonic anhydrase could influence the ability of the tubule to secrete  $\text{H}^+$  against a concentration gradient. Secondly, studies in several patients with renal tubular acidosis have shown a response to a carbonic anhydrase inhibitor acetazolamide with a further rise in urine pH and bicarbonate excretion [44]. Whether this is a normal response is still under investigation. It suggests the presence of carbonic anhydrase and its function in producing whatever urinary acidification is attained in these patients. This one finding would not exclude a quantitative deficiency of the enzyme. Taken in conjunction with the evidence that the rate at which  $\text{H}^+$  can be secreted under proper conditions is not limiting it suggests that renal tubular acidosis cannot be attributed to a primary deficiency of carbonic anhydrase. It is unlikely that the primary defect in renal tubular acidosis can be more rigorously defined until additional information is available concerning the biochemical and biophysical mechanisms involved in normal  $\text{H}^+$  exchange across the cell membrane.

#### **PATHOGENESIS OF THE COMPLICATIONS OF RENAL TUBULAR ACIDOSIS**

A brief summary of some of the clinical findings in renal tubular acidosis has already been given. It remains to review whether plausible explanations for these complications of the disease can be based on a presumed single primary tubular defect in  $\text{H}^+$  secretion.

##### *Nephrocalcinosis and Nephrolithiasis*

It has been well shown that patients with renal tubular acidosis exhibit hypercalciuria with a tendency toward hypocalcemia [6]. The administra-

infused bicarbonate was reabsorbed normally in renal tubular acidosis [42-43]. A localized proximal tubular defect would therefore appear to be untenable with the data at hand.

There is still disagreement as to whether there is a primary defect in ammonia excretion in renal tubular acidosis. In the many measurements, urinary ammonia has almost invariably been found reduced considerably below that ordinarily found in comparable systemic acidosis without kidney disease. For the urine pH attained, however, the urinary ammonia in

Fig. 39-3 Comparison of 24 hr urine pH and ammonium content in patients with renal tubular acidosis and in control subjects [15]. (By permission of the American Journal of Medicine.)

renal tubular acidosis is normal or perhaps even increased as compared to controls with acute acidosis (Fig. 39-3). In comparison with chronic experimental acidosis ammonia excretion may be somewhat diminished [37]. The close relationship between  $H^+$  concentration and the diffusion of nonionic  $NH_3$  into the urine has been previously emphasized. No determinations of glutaminase or other enzymes involved in ammonia production have been carried out on the kidney in renal tubular acidosis. All in all, the primary defect appears to lie in some aspect of  $H^+$  secretion and concentration, ammonia production being secondarily reduced because of failure to establish more favorable conditions for nonionic diffusion.

Carbonic anhydrase is the only enzyme which has been implicated in the tubular formation and secretion of  $H^+$ . Inhibition of carbonic anhydrase causes a reduction in tubular  $H^+$  secretion and may result in  $pH$ -

temic hyperchloremic acidosis. Because of this fact it has been speculated that renal tubular acidosis represents a tubular deficiency of carbonic anhydrase perhaps on a genetic basis. There is no direct evidence to support this hypothesis; its chief attraction is that of analogy. Two experimental findings moreover provide evidence against it.

Carbonic anhydrase is a metalloprotein enzyme, the only known function of which is to accelerate the attainment of equilibrium of the reaction

It does not affect the equilibrium concentration of carbonic acid (and hence of its dissociation product  $\text{H}^+$ ) but only the rate at which this equilibrium concentration is reached. Previously cited evidence from phosphate infusions demonstrates that the rate of secretion of  $\text{H}^+$  by the tubule in renal tubular acidosis is adequate given an acceptor anion to allow this secretion to continue without an adverse shift in the  $\text{H}^+$  gradient. This implies that the rate of  $\text{H}^+$  production within the cell (presumably under the influence of carbonic anhydrase) is not a limiting factor in the acidification of the urine. It is difficult to visualize how carbonic anhydrase could influence the ability of the tubule to secrete  $\text{H}^+$  against a concentration gradient. Secondly, studies in several patients with renal tubular acidosis have shown a response to a carbonic anhydrase inhibitor acetazolamide with a further rise in urine pH and bicarbonate excretion [44]. Whether this is a normal response is still under investigation. It suggests the presence of carbonic anhydrase and its function in producing whatever urinary acidification is attained in these patients. This one finding would not exclude a quantitative deficiency of the enzyme. Taken in conjunction with the evidence that the rate at which  $\text{H}^+$  can be secreted under proper conditions is not limiting, it suggests that renal tubular acidosis cannot be attributed to a primary deficiency of carbonic anhydrase. It is unlikely that the primary defect in renal tubular acidosis can be more rigorously defined until additional information is available concerning the biochemical and biophysical mechanisms involved in normal  $\text{H}^+$  exchange across the cell membrane.

#### **PATHOGENESIS OF THE COMPLICATIONS OF RENAL TUBULAR ACIDOSIS**

A brief summary of some of the clinical findings in renal tubular acidosis has already been given. It remains to review whether plausible explanations for these complications of the disease can be based on a presumed single primary tubular defect in  $\text{H}^+$  secretion.

##### *Nephrocalcinosis and Nephrolithiasis*

It has been well shown that patients with renal tubular acidosis exhibit hypercalciuria with a tendency toward hypocalcemia [6]. The administra-

tion of ammonium chloride increases the hypercalcaemia, alkali therapy quickly reduces it. The mechanism by which the renal tubular defect results in an increased clearance of calcium is not apparent largely because knowledge concerning the renal excretion of calcium is incomplete. It has been suggested that calcium is lost as one of the 'buffer bases' because of inadequacy of urine acidification [9]. On the other hand the tubular reabsorption of calcium has not been demonstrated to be dependent upon an exchange reaction with  $H^+$ . Hypercalcaemia occurs over long periods of time in a urine which is neutral or minimally acidic, creating favorable conditions for the precipitation of the calcium phosphate stones so frequently found. It has been reported that urinary excretion of citrate is low in renal tubular acidosis, another factor which would tend to favor stone formation [40]. The cause of nephrocalcinosis is not so apparent. Here calcification occurs in the renal parenchyma in a disorder associated with a decreased tendency toward precipitation of bone salts in osteoid (see below) and seemingly an increased clearance (hence a decreased tubular reabsorption) of calcium. It has been reported that acetazolamide reduces urine citrate excretion and may produce renal calcinosis in the rat [46].

### *Rickets or Osteomalacia*

Depending upon the age of the patient, rickets or osteomalacia may be found. A major and continuing source of calcium loss in the urine has been outlined above. The resulting tendency toward hypocalcaemia is thought to serve as a stimulus to increased secretion of parathyroid hormone, which acts on the renal tubule to decrease the reabsorption of phosphate and directly on bone to increase its rate of destruction. Dissolution of bone salts is also fostered by continued acidosis per se. Bone is an important source of available buffer base. Finally, there is evidence to suggest that the action of vitamin D is partially inhibited during systemic acidosis [47]. The result of these interrelated events is decreased bone because of both increased destruction and delayed calcification of osteoid. As a consequence bone pain or deformity may be the most striking disability associated with renal tubular acidosis.

### *Hypokalaemia*

Balance studies on patients with renal tubular acidosis have exhibited an increased urinary loss of potassium. In keeping with current concepts of potassium excretion by the kidney this probably represents tubular secretion of  $K^+$  in exchange for sodium. The competitive nature of the  $H^+$  and  $K^+$  exchange function in the distal tubule has been previously noted. A diminished ability to secrete  $H^+$  should therefore lead to an increased secretion of  $K^+$  by the tubule. On the other hand, repair of the acidosis by administering alkali further inhibits  $H^+$  secretion but reduces

rather than increases urinary  $\text{K}^+$  [9] In renal tubular acidosis other factors may be at play The tendency toward a negative  $\text{Na}^+$  balance may lead to a secondary stimulation of aldosterone secretion which in turn would act to increase the urinary loss of potassium [48] Potassium deficiency has been well documented with hypokalemia typical electrocardiographic changes and attacks of weakness or of flaccid paralysis—all responding quickly to replacement therapy A number of patients with renal tubular acidosis have exhibited hyposthenuria and decreased responsiveness to antidiuretic hormone In the past this has been attributed to renal damage by calcification or pyelonephritis More recently the suggestion has been offered that this may relate to the clear cell nephropathy of potassium deficiency with the resulting well-documented loss of renal concentrating ability [21]

The above summary indicates that the major clinical manifestations of renal tubular acidosis relate directly or indirectly to excessive renal loss of cations This is consistent with a single renal tubular defect characterized by an inability to concentrate hydrogen ions in the urine

### FAMILIAL INCIDENCE

The inclusion of renal tubular acidosis in a compilation of inborn errors of metabolism may be legitimately criticized Of all the clinical patterns of renal tubular dysfunction it has shown least evidence of being a hereditary disorder [49] The case histories of more than 50 patients with renal tubular acidosis have been published but the familial occurrence of the syndrome has been limited to the following few reports Schreiner Smith and Kyle [7] described renal tubular acidosis with nephrocalcinosis and nephrolithiasis in two brothers The 9 year old son of one of these patients was found to have hyperchloremia rickets and nephrocalcinosis The patient's father gave a history of repeated attacks of renal colic and exhibited mild hyperchloremic acidosis Unfortunately he refused to cooperate in further studies The disorder occurred in two siblings whose case histories have been published by Foss Perry and Wood [8] The first patient was a girl of 17 with dwarfism rickets nephrocalcinosis nephrolithiasis and a history of attacks of muscle weakness suggestive of hypokalemia Her brother who was seen at age 14 was unusually short with retardation of epiphyseal development and a history suggestive of repeated attacks of renal colic Typical chemical changes of renal tubular acidosis were found in blood and urine The father of these two patients was found to have renal calculi a urine pH of 6.8 and a rather low plasma bicarbonate level The occurrence of the syndrome in twins was reported briefly by Rendle-Short [50] One of the infants died before it was established whether or not the twins were identical The other twin was said to have made a complete recovery

In a report by Cooke and Kleeman of several patients with renal tubular acidosis a footnote was added to state that nephrocalcinosis had been found in a sibling of one of their patients [51]. No further details of this family have been reported. Engel attributed to sulfonamide intoxication renal tubular acidosis in two siblings who subsequently made complete recoveries [52]. Wilansky and Schneiderman have described a 33 year old woman with renal tubular acidosis whose father died at 60 of kidney disease with nephrocalcinosis and whose brother killed accidentally at age 20 was found to have shrunken, calcified kidneys [12]. Most patients with the syndrome do not have a history to suggest a familial occurrence. Similarly most studies of the immediate relatives of such patients have failed to detect a familial pattern. In general these surveys have been limited to a search for overt complications of the disorder such as nephrocalcinosis, nephrolithiasis, or bone disease, there has been no testing for a possible heterozygous defect such as a reduced ability to respond to an exogenous acid load. The fragmentary information available does not allow resolution of the mode of inheritance of those few cases of renal tubular acidosis which have clearly been familial. The presence of the disorder in two and possibly three successive generations suggests a dominant trait.

The rarity of a familial pattern has led to other speculations concerning etiology. It has been suggested that chronic pyelonephritis may produce in the occasional patient a selective damage to the renal acidification mechanism [6]. It is true that urinary tract infection is frequently found in this group of patients who often exhibit nephrolithiasis or nephrocalcinosis or both. Many patients especially those recognized in childhood have not had demonstrable infections. These children often seem to make a complete recovery from the disorder contrary to the adult patients. It seems more plausible to consider infection as a complication of the renal injury rather than a factor of primary etiologic importance. The simulated renal tubular acidosis produced by carbonic anhydrase inhibitors has led to the theory that sulfonamides may irreversibly damage the renal tubule to impair permanently the normal acidification mechanism. Most patients do not have a history of sulfonamide ingestion. The widespread use of more powerful carbonic anhydrase inhibitors (such as acetazolamide) over a period of a number of years has led to a few isolated reports of complicating nephrolithiasis [53] but no permanent interference with tubular function.

In summary the etiology of renal tubular acidosis in the majority of cases remains obscure. A familial occurrence has been well documented in a few incidences. Other theories of etiology such as selective renal damage from pyelonephritis or carbonic anhydrase inhibitors, have failed to account for the appearance of the disease. It is possible that a more careful search of the families of patients especially with provocative

tests such as the renal response to ammonium chloride would demonstrate a more consistent pattern of inheritance

## SUMMARY

1 Renal tubular acidosis is one of the more frequently encountered of the rare disorders of renal tubular function. It may occur as a single defect or as one component of multiple tubular defects as in the Fanconi syndrome.

2 Physiologic studies suggest that the pathogenesis lies in an inability of the tubule to attain an intraluminal hydrogen ion concentration sufficient to effect normal conservation of buffer base. Whether there is an additional defect in ammonia production has not yet been established.

3 The complications of this disorder relate to excessive urinary loss of cations particularly calcium and potassium. Calcium loss leads to rickets or osteomalacia and local complications in the kidney such as nephrolithiasis and nephrocalcinosis. Potassium loss is associated with muscle weakness and potassium deficiency nephropathy. When a compensatory amount of buffer base is supplied in the diet these complications are effectively prevented.

4 In a small number of patients renal tubular acidosis has been found as a familial disorder. Current information does not allow resolution of the mode of inheritance but the possible occurrence in three successive generations suggests a dominant trait.

5 Although studies over the past two decades have indicated the general outline of the renal defect and have led to a rational therapy the precise nature of the derangement in hydrogen ion secretion has yet to be elucidated.

## Chapter 40

### Vasopressin resistant Diabetes Insipidus

---

*Jack Orloff and Maurice B. Burg*

Vasopressin resistant diabetes insipidus is a rare congenital and familial disease characterized by failure of the kidneys to respond to antidiuretic hormone. The essential features of the disorder are polyuria, polydipsia, and the excretion of persistently hypotonic urine. The disease was first described by Forssman [1] and Waring et al. [2] who, recognizing the inefficacy of vasopressin in promoting the excretion of hypertonic urine, distinguished it from diabetes insipidus due to insufficiency of neurohypophyseal hormone. Later, Williams and Henry [3] introduced the name *nephrogenic diabetes insipidus* in order to emphasize that insensitivity of the renal tubule cells to antidiuretic hormone is responsible for all the clinical findings in the disease.

#### PHYSIOLOGY OF WATER BALANCE

In normal man the osmotic pressure of plasma is essentially a reflection of the ratio of water to solute in the body, is virtually constant (285 to 290 mOsm per kg  $H_2O$ ) despite wide variations in the intake of solute and water. Regulation is achieved by varying both the volume flow of urine and its osmotic pressure in response to changes in plasma osmolality. A fall in plasma osmolality, indicative of relative water excess, is normally attended by the excretion of large volumes of urine less concentrated than plasma. This loss of water without its equivalent content of solute (285  $\mu$ Osm for every milliliter of water) restores plasma osmolality to normal. Conversely, hyperosmolality, whether due to water loss or retention of solute in excess of water, is corrected by the excretion of urine more concentrated than plasma.

The precise adjustment of urine flow and osmolality is in large part due to the remarkable efficiency of the pituitary-renal system. The kidney is capable of varying urine flow under physiologic conditions in the adult

from less than 1 to more than 20 ml per min and urine concentration from a maximum of 1400 to a minimum of 30 to 40 mOsm per kg  $H_2O$ . These changes are effected to a considerable degree by variations in the tubular reabsorption of water largely determined by the action of the neurohypophyseal hormone vasopressin.

#### ROLE OF THE NEUROHYPOPHYSIS IN WATER BALANCE

Vasopressin, an octapeptide [4] is elaborated in the supraoptic and paraventricular nuclei of the hypothalamus [5].<sup>1</sup>

Vasopressin is thought to be stored in the posterior portion of the pituitary body from which it is secreted into the blood in response to nervous stimuli originating in cells (osmoreceptors) in the anterior hypothalamus and transmitted to the pituitary along the supraopticohypophyseal tracts [6]. On the basis of Verney's [6] classical demonstrations it has been concluded that shrinkage of the osmoreceptors due to an elevation in the effective osmotic pressure<sup>2</sup> of plasma effects the release of antidiuretic hormone (vasopressin) into the circulating blood. The resultant increase in urine osmolality restores plasma osmolality to normal thereby diminishing the rate of secretion of hormone. Conversely, a reduction in effective osmotic pressure by virtue of swelling of the osmoreceptors leads to inhibition of antidiuretic hormone release and permits the excretion of large volumes of dilute urine. It is important to recognize that graded release of hormone is essential in order to afford the continuous regulation of urine flow and concentration necessary to minimize deviations in plasma osmolality. Although the renal regulation of water balance is inadequate in the absence of a properly functioning hypothalamohypophyseal system or when the kidney is insensitive to the effect of antidiuretic hormone as in the disease under discussion the patient with either form of diabetes insipidus is capable of maintaining plasma osmolality within the normal range merely by adjusting fluid intake as long as the volume of water ingested exceeds that excreted in the urine by an amount equivalent to that dissipated in the form of

<sup>1</sup> The hormone isolated from ox pituitary by du Vigneaud and his associates is a cyclic octapeptide with the following structure [ ]

Hog vasopressin contains lysine in the penultimate position. All other mammals studied including man are thought to secrete the arginine form depicted above.

<sup>2</sup> Effective osmotic pressure is that exerted by solutes that do not penetrate cell membranes rapidly. Sodium and attendant anions represent the major osmotically effective constituents of the extracellular space. Urea on the other hand though it may contribute appreciably to the total osmotic pressure does not affect the distribution of water between cells and surrounding extracellular fluids since it penetrates cells freely and its concentration is approximately equal in the two phases.

insensible loss and perspiration excessive concentration of body fluids will not occur. In this situation, thirst rather than variable reabsorption of water assumes a regulatory role.

### RENAL REGULATION OF WATER BALANCE

Although the antidiuretic effect of vasopressin and the physiologic factors involved in its release from the hypophysis have been recognized for many years, the intrarenal events which transpire in the elaboration of hypotonic or hypertonic urine are not yet completely understood.

Fig. 40-1 Schematic representation of the nephron during water diuresis (A) and antidiuresis (B). The diagram is described in detail under The Countercurrent Theory. Although not indicated in the figure, the longitudinal interstitial osmotic gradient increases progressively from corticomedullary junction to papilla. The size of the arrows representing  $H_2O$  and  $NaCl$  reabsorption indicates the relative extent of these processes. The development of hyperosmolality in the descending limb of Henle's loop has been established only in antidiuresis. That this also occurs in water diuresis is likely but unknown. Furthermore, although hyperosmolality in the descending limb is probably the result of water abstraction, the movement of urea and other solutes from the interstitial space into the lumen also may be an important factor. The role of urea in the concentrating and diluting processes discussed in the text has been omitted from the figure.

Sufficient data derived from a variety of sources are available to justify a tentative description of the process [7-13].

In order to account for the normal variations in urine flow and concentration, the plasma ultrafiltrate formed at the glomerulus must be modified as it courses down the tubule. Two fundamental processes are involved: the selective abstraction of solute and the tubular reabsorption of water. Water reabsorption in the tubule is divided into at least three and possibly four functionally and anatomically distinct phases. On the basis of the most recent evidence, it is believed that water diffuses<sup>1</sup>

<sup>1</sup> The term diffusion is used throughout to connote movement of water across the tubular membrane. It should be recognized that this is inaccurate since bulk flow through pores along an osmotic gradient may account for most of the net movement [18].

passively out of the proximal segment the descending limb of Henle's loop the distal convoluted tubule and the collecting duct along osmotic gradients established by prior solute removal. The proximal segment and descending limb of Henle's loop are considered to be freely permeable to water under all circumstances the distal convolution and collecting duct are freely permeable only in the presence of antidiuretic hormone. Consequently variations in the permeability of the membrane to water in the latter segments impose restrictions on diffusion and permit the elaboration of urine of varying tonicity and volume. Furthermore it has been established [14] that there is a progressive increase in the osmotic pressure of the renal interstitial fluid from cortex to papilla (Fig 40-1), the medulla and papilla being hyperosmotic to plasma under all circumstances whereas the cortex is isosmotic.

Normally 20 per cent of the plasma perfusing the kidney is filtered at the glomerulus. Of the ultrafiltrate 80 to 85 per cent is reabsorbed in the proximal segment essentially as an isosmotic solution [7 8 12 15]. As noted above the luminal membrane in this area is freely permeable to water under all circumstances. Sodium and attendant anion are reabsorbed by a process involving active sodium transport (i.e. transport against an electrochemical gradient) water then diffuses passively out of the tubule along the resultant osmotic gradient. The reduced volume of isosmotic fluid is then delivered to the loop of Henle. Although the sequence of events in this segment has not been established with certainty it is probable that Wirz's [11 14] original contention that the urine is progressively concentrated as it flows downward in the descending limb and is then diluted in the upward ascent in the ascending limb is correct. In support of this are the observations (1) that urine at the tip of Henle's loop is hypertonic to plasma [12] \* and (2) that urine in the first portion of the distal convolution and therefore presumably in the ascending limb of Henle's loop is hypotonic to plasma irrespective of the final urine concentration [12 15]. In view of this it is reasonable to assume that the descending limb is freely permeable to water under all circumstances hypertonicity being effected by loss of water without solute into the surrounding hypertonic interstitium whereas the ascending limb is impermeable to water dilution being achieved by the active extrusion of sodium chloride without water. It is essential to recognize that the processes described thus far are uninfluenced by vasopressin and occur as described whether or not the final urine is concentrated or dilute. Were no other factors involved one could visualize the situation in vasopressin resistant diabetes insipidus (and in water diuresis in general) as the excretion of most of the residual hypotonic urine leaving

This has been established in antidiuretics only. No examinations of loop fluid during water diuresis have been reported. In the context of this discussion it is assumed that hypertonicity in this segment is also developed in water diuresis.

the loop of Henle. That this is an oversimplification is attested to by arguments to be presented subsequently.

The sequence of events in the distal convolution and collecting duct, unlike that in the proximal portions of the nephron, differs considerably in water diuresis and antidiuresis. In the absence of vasopressin and when a dilute urine is to be excreted, the luminal membrane in the distal nephron is thought to be relatively impermeable to water. Dilute urine which leaves Henle's loop is rendered more hypotonic by the continued abstraction of solute without water in the distal convolution and perhaps even in the collecting duct [16, 17]. Consequently urine less concentrated than plasma is excreted into the bladder. Although some loss of water along its osmotic gradient takes place in the distal nephron even in the absence of vasopressin, it is generally insufficient to effect the excretion of either an isotonic or hypertonic urine.

In marked contrast, when vasopressin is present hypertonic urine is elaborated. Antidiuretic hormone is thought to increase the permeability of the distal convolution [9-11] and collecting duct to water [11], so that for all intents and purposes these areas of the tubule function as do the proximal segment. Although electrolyte is abstracted from hypotonic urine in the distal convolution just as in water diuresis, water now diffuses freely out of the tubule until osmotic equilibrium is achieved. The remaining urine, once again isotonic to plasma, is delivered to the collecting duct where water in excess of solute is lost by movement into the hypertonic interstitium [10]. The resultant concentrated urine is excreted.

An effect of vasopressin on membrane permeability has been deduced from studies in other tissues. Koefoed-Johnsen and Ussing [18] observed a marked increase in net water movement along an osmotic gradient across isolated frog skin under the influence of neurohypophyseal extract. They concluded that the hormone produces this effect by increasing the size of pores within the skin through which water may flow. It is likely that vasopressin induces similar changes in membrane permeability in both the distal convolution and collecting duct. Wirz [10] and Gottschalk and Mylle [12] noted that urine in the distal convolution which remains hypotonic throughout during water diuresis (when antidiuretic hormone secretion is in abeyance) becomes isotonic in this segment in antidiuresis. An analogous increase in the permeability of the collecting duct to water has also been suggested by Wirz [11]. In the presence of antidiuretic hormone the osmotic pressure of collecting duct contents approximates that of the surrounding tissue and blood. Consequently, as noted above, urine made dilute by solute abstraction in Henle's loop no longer flows through essentially water impermeable conduits in the distal nephron. Instead, water in excess of solute moves out of the two areas ultimately resulting in the elaboration of hypertonic urine.

The view that water movement in all segments of the nephron including that in the collecting duct is passive has only recently been proposed. The terminal process which results in the elaboration of urine more concentrated than plasma had been assumed to be an active process since it apparently required uphill transport of water i.e. movement of water from a solution in which the activity of water is less than that of the surrounding interstitium. The argument was based on the belief that the osmotic pressure of the renal interstitial space approximated that of all other tissues of the body and was 290 mOsm per kg H<sub>2</sub>O. Wirz [14] resolved this problem and provided a rational basis for considering that water movement out of the tubule lumen is passive (along its activity gradient) even when urine is markedly hypertonic. He observed by direct cryoscopic analysis that the solute concentration of kidney water increases progressively from cortex to papilla and that both the inner medulla and papilla are markedly hypertonic to peripheral plasma. He concluded that the hypertonic environment surrounding the collecting duct provides the osmotic force necessary for passive movement of water out of this segment. He was the first to suggest that the achievement of diffusion equilibrium when the membrane is made freely permeable to water by vasopressin results in the elaboration of hypertonic urine. It is a testimony to Wirz's ingenuity to recall that hypertonicity of the medulla had been noted earlier [16] only to be ignored by most renal physiologists.

### *The Countercurrent Theory*

Wirz [15] considered the hypertonicity of the medulla and papilla (the longitudinal concentration gradient) to be due to deposition of sodium chloride transported out of the ascending limb of Henle's loop into the surrounding interstitium. Although not explicitly stated as such in his original description it is likely as noted above that loss of water without solute in the descending limb raises the concentration of the urine in this segment above that of plasma. This process concomitant concentration and dilution of urine in opposing segments of a loop like structure in which the flow of urine in one segment is counter to that of the other has a particular physiologic advantage. Since the NaCl concentration of ascending limb urine is from the beginning approximately equal to that of the environment the transport of sodium salts out of this segment is nowhere against a steep concentration gradient. This minimizes any energetic difficulties which might arise were sodium salts transported from hypotonic urine to a markedly hypertonic environment as has been suggested by Berliner et al [13].

Both the anatomic arrangement of the loop and the processes described have all the features of a hairpin countercurrent multiplier system. The principle of the multiplier has been described in detail by Hargitay and Kuhn [19] and was originally applied in a somewhat modified fashion

to the kidney by the workers and Wirz [14]. It is evident that deposition of NaCl in excess of water in the interstitial space of the medulla and papilla will raise the osmotic pressure of this area above that of the cortex. Progressive multiplication of this longitudinal gradient to the extent observed experimentally is visualized in the following manner. In a hypothetical first circulation through the loop, the intraluminal fluid has the same concentration throughout equal to that of the cortex. Active transport of NaCl from the water impermeable ascending limb lowers the concentration of ascending limb contents and raises that of the interstitial fluid and descending limb (see above). The slightly hypertonic descending limb fluid moves around through the hairpin bend in the loop into the ascending limb temporarily abolishing the concentration gradient between the opposing segments. However, continuing transport of NaCl from the ascending limb now containing fluid more concentrated than in the previous circulation, raises the osmotic pressure of the interstitial and descending limb fluids once again. Descending limb fluid more concentrated than previously moves into the ascending limb, and the process continues until in the steady state the longitudinal gradient is multiplied manyfold, whereas the small transverse gradient between loop contents and interstitium is at each point in the renal medulla equal and unchanged. In other terms the hairpin countercurrent multiplier system, by permitting transport against a minimal gradient provides the basis for multiplying the small gradient between loop contents and interstitium manyfold in the longitudinal axis.

Whether or not urinary dilution in the ascending section of the loop and concentration of the interstitial spaces occurs as described and is accomplished by a hairpin countercurrent multiplier device, sequestration or trapping of NaCl in the interstitial space in order to maintain the concentration gradient cannot be explained simply on the basis of this hypothesis. Since blood courses through this area one would expect the excess solute to be dissipated and the solute concentration never appreciably to exceed that of the inflowing blood. This aspect discussed by Wirz [20] has been emphasized and developed in detail by Berliner et al. [13]. Noting that the postglomerular capillaries in this area do not course directly through the kidney but also bend back upon each other in the shape of loops they suggested that the capillaries may act as countercurrent exchangers. This is illustrated in Fig. 40-2. Free diffusion of solute from the outflowing to the inflowing limb of the capillary loop permits recirculation of solute in the medulla minimizing the loss of excess NaCl and other solutes (notably urea) from the area. The concentration gradient is thereby maintained and not dissipated as it would be were blood flowing through in one direction only. The capillary countercurrent exchanger not only maintains the interstitial NaCl concentration indirectly providing the osmotic force necessary for the terminal con-

concentrating process but also serves to trap any urea which diffuses into the interstitial space from the collecting duct [21]. The concentration of urea in medullary water approaches that of collecting duct contents being approximately equal in antidiuresis. In view of this Berliner et al [13] have pointed out that in so far as collecting duct urea is osmotically balanced by urea in the surrounding interstitial fluid it will increase the

Fig 40-2 Principle of the countercurrent exchanger (Reproduced from Berliner et al [13] with permission of the author and publisher.)

A and B represent the effect of heating water flowing at the rate of 10 ml per min through a pipe. The addition of 100 cal per min raises the temperature 10° in both A (straight flow) and B (countercurrent flow). However, since the incoming water is heated by the outgoing water in B, the maximum temperature attained in the countercurrent system is considerably higher than with straight flow. The graph compares the temperature along the flow tubes in each system.

C, countercurrent flow as applied to the capillary loop, showing that it is not necessary for the limbs of the loop to be in direct contact. In the hypothetical illustration given, both limbs are in contact with the same interstitial fluid of progressively increasing concentration. Sodium salts (arrows) at first enter the capillary blood, later partly return to the interstitial fluid. Note the analogy between B, in which heat is recirculated, and C, in which sodium salts are similarly retained in an area.

osmotic pressure of urine beyond that attained by simple equilibration of collecting duct contents with interstitial NaCl. In other terms, the urine urea does not need to be balanced by an equivalent concentration of NaCl in the interstitial fluid, as do the other solutes. Consequently, final urine osmolality will be greater or lesser depending on the urea load presented to the collecting duct, even though no change in interstitial NaCl content occurs. The clinical significance of this is considerable. Inadequacy of urea load may limit the apparent concentrating ability of

the kidney, though no defect in either the permeability of the membrane to water or in the so-called sodium "pump" may be present [21-22].

A schematic drawing of the nephron is illustrated in Fig. 40-1. The cortex containing the glomerulus and the proximal and distal convolutions is represented as being isosmotic with peripheral plasma. The medulla and papilla in which the loops of Henle, the collecting duct, and the deeper portions of the capillary loops are embedded are represented as being hyperosmotic to plasma. Vasopressin affects only the distal convolution and the collecting duct. In diabetes insipidus or whenever vasopressin is either ineffective or not secreted, urine made dilute by transport of electrolyte out of both Henle's loop and the distal convolution loses only a small fraction of its water as it passes through the distal portions of the nephron and is excreted as such in the bladder. In the presence of vasopressin, free permeability of the distal convolution and collecting duct membrane to water permits osmotic flow of water out of the lumen. Consequently the osmolality of urine in each segment approximates that of the tubular environment, becoming isosmotic to plasma in the distal convolution and hyperosmotic in the collecting duct. It is important to recognize that the major effect of vasopressin in so far as water balance is concerned is in the distal convolution. The promotion of osmotic equilibrium in this area and the formation of isosmotic urine results in the restoration of as much as  $\pm 15$  per cent of the filtered water to the body, whereas the reduction in volume in the collecting duct, though resulting in urine hypertonicity, restores considerably less ( $\pm 5$  per cent).

#### FACTORS OTHER THAN VASOPRESSIN

##### *Effects of Filtration Rate*

In order properly to evaluate the significance of changes in urine flow and osmolality in patients suspected of having vasopressin-resistant diabetes insipidus, it is essential to recognize the influence of at least two other factors: filtration rate and solute excretion on the concentrating process. Berliner and Davidson [23] have demonstrated that a reduction in filtration rate may, even in the absence of vasopressin (or at least when its secretion is minimal and constant), promote the excretion of hypertonic urine. Presumably volume flow of hypotonic urine to the collecting duct is significantly diminished by this procedure. Consequently, although outward movement of water in the terminal segment is minimal under these circumstances, it may be sufficient to concentrate the small volume of urine delivered to the collecting duct. In view of this observation, minor increases in urine osmolality in diabetes insipidus following dehydration need not necessarily signify residual antidiuretic hormone activity. On the other hand, it is not at all certain that the elaboration of hypertonic

urine in patients with the pituitary disorder following protracted dehydration or manipulations designed to reduce filtration rate can uniformly be ascribed to the fall in filtration rate itself. Residual antidiuretic hormone activity can never be completely excluded except in patients with the severe form of vasopressin resistant diabetes insipidus. In one such patient although urine osmolality rose during dehydration in association with a fall in filtration rate it never exceeded that of plasma [24].

### *Effects of Solute Excretion*

The influence of solute excretion on urine flow and concentration is clinically of greater significance than the effect of filtration rate. Osmotic diuretics diminish water and solute reabsorption in the nephron and result in the excretion of large volumes of essentially isosmotic urine whether or not vasopressin is acting. Both sodium transport and water reabsorption are interfered with in the proximal segment because of the osmotic restraint of nonabsorbed intraluminal solute. Consequently a larger than normal volume of isosmotic urine enters the more distal portions of the nephron overwhelming the capacity of the segment to modify the concentration of the urine. Urine osmolality rises in osmotic diuresis both in patients with nephrogenic diabetes insipidus [25] and in normal persons [26] during antidiuretic hormone suppression whereas in hydropenic subjects in whom vasopressin is acting the converse a progressive fall in osmolality occurs [27]. In both instances urine osmolality approaches that of unmodified glomerular filtrate as the fraction of proximal urine delivered to the distal segment increases.

It is important to emphasize that no fundamental processes other than proximal reabsorption need be disturbed during osmotic diuresis to account for the observations. It is probable that in the presence of vasopressin more water is actually removed in the collecting duct during solute diuresis than at low rates of solute excretion [28]. That this does not result in the achievement of maximal hypertonicity is due in part at least to the resultant dilution of the medullary interstitial space. Even were osmotic equilibrium to obtain in this segment which is unlikely during the rapid flow of solute diuresis the maximal osmotic pressure which could be obtained would be considerably less than normal.

The effects of osmotic diuresis are more easily visualized if one considers as do Wesson and Anslow [10] that hypotonic urine is made up of two hypothetical moieties: (1) an isosmotic portion (referred to as the osmolar clearance) equal in volume to the number of milliliters of fluid containing all the urine solute at the concentration of plasma; and (2) an additional amount of distilled water (referred to as solute-free water) equal in volume to that which would have to be added to the isosmotic moiety to reduce its concentration to that observed. Hypertonic urine on the other hand is

depicted as being made up of an isosmotic portion less that amount of solute-free water which would have to be abstracted from it to produce the observed hypertonicity (referred to as negative solute-free water). In this view, the removal of solute from isosmotic filtrate (the process of urinary dilution) results in the elaboration of solute free water, and conversely the abstraction of solute-free water from isosmotic filtrate results in the addition of negative-free water to the interstitium and the production of hypertonic urine. Clearly, even were the amount of solute-free water formed in water diuresis or the amount of negative free water abstracted in antidiuresis unchanged in osmotic diuresis, urine concentration would approach isotonicity asymptotically with increasing urine flow since an increasingly greater fraction of the final urine would be composed of what may be considered nonabsorbed proximal isosmotic fluid.

In the light of these concepts it is not possible to assess the clinical significance of changes in urine concentration without consideration of the rate of solute excretion. In this regard the *posthenuria* of renal insufficiency as has been pointed out by Baldwin et al [29] and Platt [30], may be a consequence of the high rate of solute excretion relative to the diminished filtration rate and does not necessarily denote either an inability to concentrate the urine or a vasopressin unresponsiveness. The filtered load of urea per nephron is markedly increased in azotemia limiting the capacity of the kidney to elaborate either a maximally hypertonic or hypotonic urine. The extremes of urine osmolality are observed only when solute excretion per nephron is minimal.

Even in the absence of antidiuretic hormone as noted above, water may diffuse out of the relatively impermeable distal segment and collecting duct although at a considerably lesser rate than when vasopressin is present [20-31]. In the course of solute diuresis in vasopressin resistant diabetes insipidus Orloff and Walker [20] noted (Fig 40-3) not only a progressive rise in urine osmolality but also an increasingly greater rate of solute free water excretion. They concluded that this phenomenon is in part due to a progressive decline in the rate of outward diffusion of water initially freed in Henle's loop and the distal convolution as a consequence of the osmotic restraint of intraluminal solute. Thus the presence of solute in tubule urine decreases the activity of water and thereby its rate of outward diffusion in both the distal convoluted tubule and collecting duct. Even in the presence of vasopressin maximal solute diuresis may so limit outward diffusion of water as to result in the excretion of hypotonic urine. Results of this nature have been observed during vasopressin administration in patients with pituitary diabetes insipidus [32] and in dogs undergoing combined water and solute diuresis [31]. This is not a reflection of insensitivity to vasopressin but indicates that despite relatively free permeability to water in the distal nephron the reduction in both the transit time and the osmotic gradient prevents the attainment of diffusion equilibrium and permits the delivery of large volumes of

hypotonic rather than isotonic urine to the terminal concentrating site. In view of these observations it is important to determine the normal relationship between urine osmolality and solute excretion before ascribing isosthenuria (see above) or even hyposthenuria<sup>5</sup> to true vasopressin insensitivity.

Fig 40-3 The relationship between urine flow and solute excretion in a 10-year-old girl with vasopressin resistant diabetes insipidus. The diagonal line represents the excretion of isotonic urine; the curvilinear line that observed experimentally. The difference between the hypothetical and observed lines represents a solute-free water excretion ( $C_{H_2O}$ ) which rose progressively throughout the study.

## CLINICAL ASPECTS

Vasopressin resistant diabetes insipidus manifests itself soon after birth, but since polyuria in infancy is rarely considered a symptom of disease even in the first born of the most apprehensive parent, it is frequently undiagnosed in early life. Furthermore the presenting signs which in fact may be alarming are often nonspecific, being those associated with severe dehydration: fever, convulsions in infants, vomiting, constipation, and hyperosmolality. The characteristic syndrome—polydipsia, polyuria, and persistent hyposthenuria (specific gravity generally

The excretion of urine less concentrated than plasma

less than 1 005<sup>6</sup>)—diagnostic in offspring of affected families is noted only when hydration is adequate Under these circumstances, other causes of dehydration can generally be excluded

### RESPONSE TO VASOPRESSIN

In contrast to what occurs in diabetes insipidus of pituitary origin, neither the copious urine flow nor the low urine concentration is affected by the administration of large doses of vasopressin (Table 40-1) Nor is it

TABLE 40-1 LACK OF EFFECT OF PURIFIED VASOPRESSIN IN A 12 YEAR-OLD MALE WITH VASOPRESSIN RESISTANT DIABETES INSIPIDUS

| Time min | V ml/min   | U m | P m | GFR ml/min |

possible to effect a diminution in flow or the elaboration of a hypertonic urine by stimuli known to enhance secretion of vasopressin from the pituitary body This is illustrated in Table 40-2 Although severe dehydration may ultimately result in a rise in urine osmolality and an associated fall in urine flow urine hypertonicity has not been observed in patients totally unresponsive to vasopressin under these circumstances [24-33]

Mild forms of the disease, characterized by partial responsiveness to vasopressin may exist in females of affected families Carter and Simp

\* Specific gravity measurements have been used for many years to estimate urine concentration Since the former is a measure of urine density rather than of solute concentration and is dependent on both the weight and volume displacement of urine solids it cannot be used as a precise estimate of osmotic pressure This can be determined only by measuring the concentration of osmotically active constituents in urine by determining either the freezing point or vapor pressure of the urine Despite this there is a reasonably good correlation between urine specific gravity and osmotic pressure Significant discrepancies are observed only when abnormal solutes (glucose protein) constitute a large fraction of the total urine solute Under these circumstances specific gravity gives a falsely high estimate of urine concentration The converse a low estimate has been reported by Miles et al [34] when urea is present in high concentration in urine The limits of urine osmolality as determined by cryoscopic analysis have been referred to earlier Patients with nephrogenic diabetes insipidus generally cannot elaborate urine more concentrated than 50 to 100 mOsm although during solute diuresis urine osmolality may approach isotonicity (280 mOsm) as a limit Urine specific gravity is less than 1 005 approaching 1 010 during osmotic diuresis

kiss [35] observed that female siblings and relatives of patients with the full blown disorder were able to concentrate their urine to approximately 1 018 to 1 019 following 12 hr of dehydration. Although this is significantly less than normal it does represent a considerable degree of responsiveness. *Forsman [1] has reported similar findings. Furthermore Childs and Sidbury [36] have stated that two mothers of patients with the disease responded minimally to exogenous vasopressin. Neither was able to elaborate a hypertonic urine. Apparently although full expression of the renal defect may occur in both females and males incomplete excretory capacity has thus far been reported only in females.*

In all forms of the disease dehydration and its consequences are the most frequent complications as well as the most common causes of death. The high infant mortality in affected families is undoubtedly ascribable to this. The reported association of hydronephrosis and bladder hypertrophy in some affected individuals is probably secondary to polyuria and voluntary retention.

#### MENTAL AND PHYSICAL RETARDATION

A number of authors have commented on the relatively high incidence of mental and physical retardation in children with this disorder [3, 37-42]. It is not at all clear that these are primary accompaniments of the renal defect. More likely structural brain damage if present is secondary to repeated episodes of severe dehydration [38, 39] and to the altered growth pattern occasioned by inadequate food intake because of the exhausting influence of uncontrolled polydipsia. *Hallman et al [42] observed that an infant suffering from the disease became so exhausted from polydipsia when subsisting on a regular diet that he was unable to eat and play normally. Mental performance and nutritional status were*

improved by altering the protein and salt content of the diet so as to decrease obligatory solute and water loss. The reduction in polyuria diminished the time required for drinking and enabled the child to play, eat, and sleep adequately.

### RENAL FUNCTION

The only physiologic abnormality present in the disease is defective water reabsorption. In all other respects renal function may be considered to be normal. Renal blood flow, glomerular filtration rate, glucose, phosphate and amino acid transport, as well as other discrete tubular functions, may be unaffected [2, 3, 25, 37, 41]. Changes in filtration rate and plasma flow which have been observed by some authors may have been due either to dehydration or associated but unrelated structural disease. Abnormalities of acid base balance and electrolyte metabolism are excluded by the normal plasma electrolyte patterns observed when hydration is adequate.

### PATHOGENESIS

The pathogenesis of the disease is unknown. Antidiuretic substance has been found in the blood [41, 43] and urine [40, 44, 45] of patients, indicating that endogenous hormone is produced. Furthermore the administration of large doses of vasopressin, which is without effect on urine flow and concentration, results in abdominal pain and blanching, known side effects of the hormone [41, 44, 46, 47]. This indicates that rapid inactivation of the hormone within the body is not responsible for the disease. No information is available relative to the normal *in vivo* metabolism of vasopressin in man. It has not been ascertained whether the hormone may be inactivated in an abnormal fashion by the pertinent tubule cells. In view of recent evidence that vasopressin is bound to renal tissue during antidiuresis [45], it is possible that normal "binding" does not occur in vasopressin-resistant diabetes insipidus. Other preparations of vasopressin, the synthetic arginine and lysine forms, are also ineffective [47].

No structural basis for the disorder has been found. Gross and microscopic examination of renal tissue by the usual techniques has not been revealing [2, 37, 40, 41, 49]. Although MacDonald [41] reported some shortening of the proximal segment in a microdissected specimen from one child, Darmady [49], who has examined one infant and two adults with the disease, has not been able to find any abnormality by microdissection or by histologic techniques.

On the basis of all the studies, it is assumed that end-organ unresponsiveness (presumably in the distal convolution and collecting duct) is responsible for the inefficacy of the hormone. The resultant fixed im-

permeability of the distal nephron to water probably does not differ from that normally occurring in man during water diuresis since the relationship between solute excretion and urine osmolality is the same in both groups [47]

## DIAGNOSIS

The diagnosis is established without difficulty in the adequately hydrated subject in whom no response to vasopressin is observed. Other causes of isosthenuria or hyposthenuria may be mistaken for the incompletely expressed form of the disease. However the characteristic findings of the underlying disorder should preclude errors in diagnosis. Diminished ability to concentrate urine maximally has been observed in hypokalemic nephropathy [50], hypercalcemia [51], sickle cell disease [52], so-called water losing nephritis [53], and postobstructive uropathy [54]. In all but the last of these although the urine is hypertonic to plasma following vasopressin it is not maximally concentrated. Isosthenuria in renal insufficiency is due in large part to solute diuresis (see above) and is generally not attended by true unresponsiveness to vasopressin. Although it is possible that some patients may have structural disease with resultant insensitivity to vasopressin this has not been established. Whether the reports of decreased concentrating ability in tubular acidosis [55] and in congenital tubular defects associated with aminoaciduria [56] are indicative of true unresponsiveness to vasopressin cannot be established on the basis of the available evidence.

Psychogenic polydipsia may be associated with diminished responsiveness to vasopressin [57]. DeWardener [58] observed a reversible limitation in concentrating ability in these and in normal subjects following prolonged chronic and excessive water ingestion. DeWardener [57] has also stated that patients with the pituitary disorder may demonstrate this on occasion. The cause of the temporary alteration in tubule permeability is unknown. Prolonged administration of vasopressin and water in both man and dog may also be associated with an apparent diminution in responsiveness to the hormone [59-61].

### *Hereditary Pituitary Diabetes Insipidus*

Although the distinction between pituitary diabetes insipidus and the renal form generally is not difficult, mild cases of vasopressin resistant diabetes insipidus have been confused with hereditary pituitary diabetes insipidus [1]. The latter disorder is familial and also appears in early infancy. However it is a less severe disease than the fully expressed form of vasopressin resistant diabetes insipidus. Consequently dehydration and retarded development are uncommon. Nonspecific atrophy of the posterior lobe of the pituitary and hypoplasia of the paraventricular and

improved by altering the protein and salt content of the diet so as to decrease obligatory solute and water loss. The reduction in polyuria diminished the time required for drinking, and enabled the child to play, eat, and sleep adequately.

### RENAL FUNCTION

The only physiologic abnormality present in the disease is defective water reabsorption. In all other respects renal function may be considered to be normal. Renal blood flow, glomerular filtration rate, glucose, phosphate and amino acid transport, as well as other discrete tubular functions, may be unaffected [2, 3, 25, 37, 41]. Changes in filtration rate and plasma flow which have been observed by some authors may have been due either to dehydration or associated but unrelated structural effects. Abnormalities of acid base balance and electrolyte metabolism are excluded by the normal plasma electrolyte patterns observed when hydration is adequate.

permeability of the distal nephron to water probably does not differ from that normally occurring in man during water diuresis since the relationship between solute excretion and urine osmolality is the same in both groups [47]

## DIAGNOSIS

The diagnosis is established without difficulty in the adequately hydrated subject in whom no response to vasopressin is observed. Other causes of isosthenuria or hyposthenuria may be mistaken for the incompletely expressed form of the disease. However the characteristic findings of the underlying disorder should preclude errors in diagnosis. Diminished ability to concentrate urine maximally has been observed in hypokalemic nephropathy [50], hypercalcemia [51], sickle cell disease [52], so called water losing nephritis [53], and postobstructive uropathy [54]. In all but the last of these, although the urine is hypertonic to plasma following vasopressin, it is not maximally concentrated. Isosthenuria in renal insufficiency is due in large part to solute diuresis (see above) and is generally not attended by true unresponsiveness to vasopressin. Although it is possible that some patients may have structural disease with resultant insensitivity to vasopressin, this has not been established. Whether the reports of decreased concentrating ability in tubular acidosis [55] and in congenital tubular defects associated with aminoaciduria [56] are indicative of true unresponsiveness to vasopressin cannot be established on the basis of the available evidence.

Psychogenic polydipsia may be associated with diminished responsiveness to vasopressin [57]. DeWardener [58] observed a reversible limitation in concentrating ability in these and in normal subjects following prolonged chronic and excessive water ingestion. DeWardener [57] has also stated that patients with the pituitary disorder may demonstrate this on occasion. The cause of the temporary alteration in tubule permeability is unknown. Prolonged administration of vasopressin and water in both man and dog may also be associated with an apparent diminution in responsiveness to the hormone [59-61].

### *Hereditary Pituitary Diabetes Insipidus*

Although the distinction between pituitary diabetes insipidus and the renal form generally is not difficult, mild cases of vasopressin resistant diabetes insipidus have been confused with hereditary pituitary diabetes insipidus [1]. The latter disorder is familial and also appears in early infancy. However, it is a less severe disease than the fully expressed form of vasopressin resistant diabetes insipidus. Consequently dehydration and retarded development are uncommon. Nonspecific atrophy of the posterior lobe of the pituitary and hypoplasia of the paraventricular and

supraoptic nuclei have been observed at autopsy. According to Forssman [1] two forms of this disease exist, one transmitted as a sex linked recessive the other as an autosomal dominant.

## GENETICS

The renal form of diabetes insipidus is an inherited disease which appears with greater frequency in male members of affected families than in females. It was originally considered by Forssman [1] and Williams and Henry [3] to be transmitted as a sex linked recessive characteristic. All of the 17 patients examined by these authors were males whose parents and female siblings were thought to be unaffected. Furthermore the female siblings repeatedly passed the trait on to their male offspring. No example of male to male transmission was observed. It has since been established that the disease is not completely recessive in female heterozygotes [3a]. Although all the males thus far reported exhibit complete unresponsiveness to vasopressin, mild forms of the disease have been observed in female siblings and relatives of affected males [1, 3a]. In addition in families in which there is no evidence that the fathers were affected several females have been reported in whom the disease is fully as severe as in males [3a, 44, 62, 63]. On the basis of these observations it appears that nephrogenic diabetes insipidus is a dominant sex linked disorder with variable expressivity in heterozygous females. If this is so mothers and half of the sisters of affected males should either be carriers of the defect or exhibit some form of the disease. More careful studies in the future may establish this. In the only affected families studied with this in mind 12 of 17 females examined were unable to concentrate their urine normally following dehydration [3a]. The discrepant preponderance of male patients in other sibships may indicate either a low degree of penetrance in females, a failure to recognize cases with low expressivity, or lowered viability and fertility of those affected males whose daughters would otherwise provide the excess female morbidity. The severity of the symptoms in all the males reported in the literature may be indicative of a high degree of expressivity in this sex. However no systematic study has excluded the possibility that male hemizygotes may show variable expressivity between and within kindreds as do heterozygous females.

Childs and Sidbury [36] although conceding that the disease is most reasonably viewed as due to a gene occupying the X chromosome and showing perhaps intermediate dominance have suggested an alternative hypothesis: an autosomal dominance with some degree of sex limitation. The latter view of the mode of inheritance has been emphasized by Cannon [62]. He described a large pedigree in which 4 of 55 affected males were reported to have affected sons. Cannon explained this pedigree by assuming that in some kindreds at least the disease is an autosomal

dominant with low penetrance in females. Allen [64] has pointed out that Cannon's pedigree conforms closely to sex-linked inheritance with the exception of the 4 cases of male to male transmission. If inheritance were autosomal, half the male offspring of affected males should have the disease and only half the female offspring of such males should be carriers. According to Cannon's pedigree chart, only 6 of the 44 male children were affected and of 19 females who had children 16 were affected or had affected children. Either of these discrepancies alone is sufficient to preclude an autosomal theory of inheritance in this family.

## TREATMENT

There is no specific therapy for the disease. Adequate hydration easily achieved in the adult by allowing free access to water is essential to prevent the deteriorating effect of repeated episodes of dehydration. Obligatory water loss may be minimized by reducing solute intake [39-42]. This, however, is rarely necessary except in infants. It has been reported recently that chlorothiazide, a potent diuretic, may induce satisfactory remissions in this disorder [65].

The therapy of the acute episode of dehydration may differ from that in other situations. If sufficient water can be administered orally, hyperosmolality of body fluids is easily overcome. On the other hand, if parenteral therapy is necessary, 5 per cent dextrose in water, although the fluid of choice in other instances of dehydration, may aggravate the hypertonicity. Orloff and Walser [47] observed that the rapid infusion of isosmotic dextrose in water in nephrogenic diabetes insipidus, in so far as it produces solute diuresis (glycosuria), will so increase solute-free water excretion as to promote the development of hyperosmolality and cellular dehydration. The dextrose is not metabolized with sufficient speed to release solute-free water in excess of that excreted in the urine. It is apparently virtually impossible to maintain positive water balance if 5 per cent dextrose is administered to patients with this disorder. Successful correction of hyperosmolality may be accomplished by administering 2½ to 3 per cent dextrose in water, since under these circumstances it is possible to limit the extent of the urinary solute and water loss. It is advisable to administer water without solute orally as soon as is clinically feasible.

## SUMMARY

1. Vasopressin-resistant diabetes insipidus is a renal disorder characterized by polydipsia, polyuria, and the excretion of persistently hypotonic urine. It is distinguished from diabetes insipidus due to in-

Intravascular hemolysis is not observed if 2½ to 3 per cent dextrose in water is administered parenterally. Less concentrated solutions may be hazardous.

sufficiency of antidiuretic hormone by a lack of response to exogenous vasopressin

2 All males thus far reported are completely unresponsive to antidiuretic hormone. Mild forms of the disease, in which a limited response to vasopressin occurs, are observed in some female members of affected families

■ The only known defect present in the disease is insensitivity of the renal tubule cells to vasopressin. No anatomic or biochemical basis for the end organ unresponsiveness has been determined. The hormone normally accelerates the passive reabsorption of water in the distal nephron ultimately resulting in a reduction in urine flow and a rise in urine osmolality. In its absence, or when the pertinent tubule cells are insensitive to its effect, water diuresis is continuous

4 The only established treatment is maintenance of water balance by ingestion of adequate amounts of water. In infants it is sometimes necessary to reduce the water requirement by restricting solute intake. Life expectancy is normal if episodes of dehydration are prevented by permitting free access to water under all circumstances. Chlorothiazide has induced remissions in some cases

5 The genetic pattern of the disorder is consistent with transmission as a sex-linked dominant characteristic with variable expressivity in females. The suggestion that an autosomal form of inheritance may be present in some families is not fully supported by the available data

## Chapter 41

### Glycinuria

---

*James B Wyngaarden*

In 1957 DeVries Kochwa Lazebnik Frank and Djaldetti [1] reported a family in which excessive urinary excretion of glycine was found in association with nephrolithiasis. The glycinuria appeared to be due to a selective renal tubular defect of glycine reabsorption and was not accompanied by unusual loss of other amino acid phosphate or glucose. A kidney stone obtained from one patient was composed chiefly of calcium oxalate but also contained a small amount of extractable glycine. To date this is the only report of what is probably a very rare disease.

#### CLINICAL SYNDROME IN THE INDEX CASE

This disorder was first recognized in a 20 year old woman whose initial urologic symptoms occurred at 2 years of age when she had fever associated with pus in the urine. The first of a series of attacks of renal colic occurred 3 years later. Renal lithiasis was recognized roentgenographically at age 6. One pyohydronephrotic kidney was removed at 11 and 8 years later a calculus developed in the remaining kidney. Examination then showed many calcium oxalate crystals in the urine but no infection. When the patient was 19 pyelotomy was performed and the stone was removed. On a high fluid intake the urine subsequently showed a trace of albumin but no cells casts or crystals.

#### METABOLIC STUDIES IN GLYCINURIC SUBJECTS

The urine of the patient was found to contain unusual amounts of glycine but normal quantities of other amino acids. Initial studies were performed by two-dimensional paper chromatography. Quantitative estimations of the amount of glycine in the urine were obtained by a microbiologic assay. Six members of the patient's family were also

examined and glycine excretion was abnormally high in three. Two family members also gave a history of renal colic. Data on these family members are shown in Table 41-1. It will be noted that abnormal glycine excretion was found in a total of four individuals, all women representing three successive generations.

TABLE 41-2 INTRAVENOUS GLYCINE LOADING STUDY

| Subject    | Urinary free glycine load, mg |         |
|------------|-------------------------------|---------|
|            | 0 min                         | 200 min |
| Normal     | 40                            | 334     |
| Normal     | 50                            | 340     |
| Glycinuric | 800                           | 1240    |

Each subject received 1 gm glycine per 10 lb body weight in 70 ml saline solution within 2½ min.

SOURCE DeVries et al [1]

The serum level of glycine in three glycinuric individuals was normal as judged by a semiquantitative paper chromatographic evaluation. Consequently it was believed that the glycinuria could not be attributed to overflow secondary to hyperglycinemia. A disturbance of renal tubular reabsorption of glycine was therefore postulated. Studies of glycine excretion following intravenous infusion of glycine showed a significantly greater urinary load of glycine in the original patient than in two normal subjects similarly investigated (Table 41-2). The urinary

glycine excretion of the glycinuric subject was not influenced by 11 days of ingestion of a diet containing only 30 gm protein per day

The stone which was obtained was composed mainly of calcium oxalate but free glycine was extractable from the stone at room temperature with 1 N HCl and proved to be of the order of 0.3 per cent of the dry weight of the stone. No glycine was found in eight random oxalate stones obtained from other patients. The possibility of an abnormal degree of conversion of glycine to oxalate via glyoxylate (cf Chap 14) was considered but the urine contained only 18 to 40 mg oxalate per day on nine consecutive days and glyoxylic acid could not be demonstrated in her urine.

Additional studies on two members of this family revealed normal calcium excretions on a regular diet, normal responses to intravenous calcium infusions and normal phosphorus clearances. No glycosuria or abnormal xanthinuria was detected in the proband. Except for the maternal grandmother, no family members showed evidence of decreased bone density by roentgenographic study. Thus these subjects appeared to exhibit a disorder different from those reported by Evered [2] whose patients showed glycinuria, hypophosphatemia, hyperphosphaturia and prolinuria associated with osteomalacia (cf Chaps 36 and 37).

## SOME ASPECTS OF NORMAL GLYCINE METABOLISM

Glycine is abundantly present in the diet and is found in all proteins. It is a nonessential amino acid and is readily synthesized by the majority of living organisms. The principal source of nondietary glycine in the animal body is serine [3, 4] which can be readily transformed into glycine by loss of its  $\beta$  carbon as formyl. A second source is by transamination of glyoxylic acid from glutamic acid. Glycine can also be generated by catabolism of sarcosine or of ingested threonine.

Glycine is an important compound in many biosynthetic pathways. In addition to its role in protein synthesis and its ready transformation into intermediates of carbohydrate metabolism, glycine is directly involved as a precursor of purines, porphyrins, glyoxylic and oxalic acids, serine, glutathione, sarcosine, creatine and glycocholic acid. It is found in urine as the benzoyl peptide, hippuric acid, and also forms conjugates with certain steroids, valicylates, and Bromsulfalein.

Estimates of the glycine pool have been made in rats and more recently in man. Arnstein and Neuberger [5] estimated that the readily available glycine pool of the rat is of the order of 100 mg per kg body weight. Watts and Crawhall [6] estimated the glycine pool in man to be 80 mg per kg on the basis of measurements of the specific activity of free urinary glycine following administration of glycine  $C^{14}$ . Gutman, Yu, Black, Yalow, and Berson [7] estimated the glycine pool in man to be

83 mg per kg from the ratio of isotope incorporation of glycine 1 C<sup>14</sup> into urinary uric acid under tracer and load conditions

The glycine pool is not homogeneous. Arnstein and Neuberger [5] have evidence for a second glycine pool in rats which is in slow equilibrium with the first or readily available glycine pool. Glycine was withdrawn from it in response to large doses of benzoate. Benedict, Kalinsky, Scarrone, Wertheim and Stetten [8] observed that there are significant differences in labeling of hippurate and the sarcosine moiety of creatine in dystrophic subjects following oral administration of glycine N<sup>15</sup>. They suggest that there are at least two glycine pools in poor equilibrium with one another. Also, Watts and Crawhall [6] observed a greater isotopic labeling of the glycine moiety of hippurate than of free urinary glycine in man following oral administration of glycine 1 C<sup>13</sup>. Presumably, the hepatic glycine pool was preferentially labeled under this circumstance.

The rate of turnover of glycine has been estimated in several species. In the rat and guinea pig the daily biosynthesis of glycine was estimated to be about 2 and 3 gm per kg per day respectively [3, 6] and these values were not significantly influenced by restriction of glycine intake [3] or by vitamin B<sup>12</sup> or ascorbic acid deficiency, but were reduced in folic acid deficiency [9]. Watts and Crawhall [6] estimated the turnover of glycine in man to be only 1.0 gm per kg per day.

The plasma levels of glycine normally range from 1.15 to 1.92 mg per 100 ml as determined by resin column chromatography [2, 10] and 1.47 to 2.83 mg per 100 ml as determined chemically [11]. By the latter method the values for whole blood are higher (1.76 to 3.02 mg per 100 ml) because of the greater concentration of glycine in the red cell (1.64 to 3.73 mg per 100 ml). Variations of concentration of glycine in plasma, blood or red cells have been reported in disease [11]. Plasma glycine levels decrease significantly (20 to 32 per cent) following oral ingestion of 10 gm sodium benzoate [12].

## RENAL HANDLING OF GLYCINE

### *Normal Mechanisms*

The normal urinary excretion of free glycine is 70 to 200 mg per day as determined by column chromatographic [2, 10] or microbiologic methods [1]. A considerably larger amount of glycine is excreted in conjugated form and is released by acid hydrolysis [2, 10]. The total glycine excretion may normally amount to 800 to 1,125 mg per day.

Glycine clearance has been estimated in only a few subjects. It ranges from 1.5 to 5.7 ml per min [2]. Presumably glycine is freely filtered at the glomerulus and quite efficiently reabsorbed in the renal tubules. The mechanism by which it is reabsorbed is not well understood. Such studies as are available have been performed chiefly in the dog. Pitts's [13] data indicate that glycine and creatine are reabsorbed by a common mecha-

nism since as the filtered load of glycine is increased creatine reabsorption decreases and is reduced to zero when the reabsorptive mechanism is saturated with glycine. On the other hand elevation of plasma creatine concentration had no significant effect on reabsorption of glycine. Thus the reabsorptive mechanism has a much higher affinity for glycine than for creatine. Since at sufficient loads alanine and glutamic acid also interfere with creatine reabsorption and since moderate elevations of plasma glycine significantly depress reabsorption of arginine Pitts subsequently [14] suggested that these four amino acids and creatine are reabsorbed by a common mechanism. It was also suggested that phosphate reabsorption shares a common element with alanine and glycine since elevation of plasma levels of the  $\alpha$  amino acids depresses phosphate reabsorption [15]. Beyer Wright Skeggs Russo and Shaner [16] were unable to confirm Pitts' finding that glycine depresses reabsorption of arginine.

Arginine and glycine may not be reabsorbed by a common mechanism in man. The aminoaciduria of cystinuria involves cystine lysine ornithine and arginine but not glycine [17] whereas certain aminoacidurias involving glycine do not involve arginine [18]. Indeed the recognition of glycinuria as an isolated reabsorptive defect was interpreted by DeVries and collaborators as evidence that glycine is handled by a tubular reabsorptive mechanism of unique specificity for this amino acid in man. While this may be correct an alternative explanation is that a single enzyme normally responsible for glycine alanine and creatine reabsorption (and perhaps of other substances) has selectively lost its ability to bind glycine through a minor structural alteration which is of no consequence for the binding of other substrates. Variation in a single amino acid of the peptide chain of the enzyme as in hemoglobins A S and C [19] might hypothetically have such a consequence. It would be of interest to know whether the glycinuric subjects of DeVries and collaborators also excreted excessive quantities of creatine.

#### *Renal Mechanism in Glycinuric Patients*

The reabsorptive defect in the glycinuric subjects was of impressive degree. The clearance of glycine approximated 70 ml per min in the index case a value perhaps fifteen times normal and larger than the glycine clearance reported by Levered [2] in patients with the adult Fanconi syndrome (41 ml per min) or Hartnup syndrome (29 ml per min) in whom a generalized aminoaciduria was present. In the subjects with glycinuria the excretion of free glycine ranged from 593 to 1 000 mg per day. In subjects with various oligo- or generalized aminoacidurias [2 13 19] the excretion of free glycine has ranged from 220 to 1 010 mg per day. Even the largest of these values approximates only 3 per cent of the daily glycine turnover in man. It is therefore not surprising that the plasma levels of glycine have been essentially normal in the glycinuric

subjects [1] and also in subjects with adult Fanconi and Hartnup syndromes [2] and Wilson's disease [19]

The relationship between excretion of glycine and formation of calcium oxalate stones in the glycinuric subjects remains obscure. Excessive conversion of glycine to oxalate seems quite improbable in view of normal urinary values of oxalate. The one stone which has been examined contained glycine which resisted simple elution with water but which was readily extractable in 30 min at room temperature in 1 *N* HCl. This finding should differentiate this type of oxalate stone from those commonly encountered in nonglycinuric subjects.

### GENETICS

Glycinuria is inherited as a dominant condition possibly sex limited, in the only available pedigree (Fig. 41-1). The pedigree is too small to

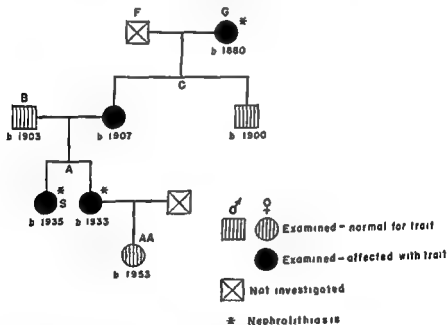

Fig. 41-1 Pedigree of glycinuria (Redrawn from Delvaux et al. [1])

establish sex limitation with certainty or to determine whether the trait is transmitted by an autosomal or sex chromosome.

### SUMMARY

1 Glycinuria is a rare disorder which has been recognized in four female members of three generations of a single family. It appears to be due to a selective renal tubular defect of glycine reabsorption.

2 Three of the glycinuric subjects had nephrolithiasis. The only stone analyzed was composed chiefly of calcium oxalate but it also contained a small amount of extractable glycine. The excretion of oxalate in the urine was normal.

3 The pedigree of the glycinuric family suggests that the disorder is transmitted as a dominant character possibly sex limited.

## Chapter 42

### Cystinuria\*

---

*W Eugene Knox*

✓ Cystinuria was one of the four diseases singled out by Garrod in 1908 [1] as the 'inborn errors of metabolism'. He postulated that cystinuria was due to a block in oxidation of cystine to sulfate. Increasing understanding of this disease has necessitated revision of Garrod's original concept and expansion of the 'inborn errors' to include not only hereditary defects of dissimilative and synthesizing enzymes but also defects of certain other functional systems such as renal tubular transport mechanisms.

✓ Cystinuria is now known to be a hereditary anomaly of renal function in which there is impaired renal tubular reabsorption of cystine, lysine, arginine, and ornithine. These amino acids, two of them essential to the body, are excreted in the urine in abnormal amounts throughout life. Only the excretion of the least soluble one, cystine, was recognized until recent times, and both the name and the clinical importance of the condition are entirely referable to this one amino acid. The only clinical consequence appears to be the frequent formation of urinary calculi composed of almost pure cystine. Some of the individuals heterozygous for the trait of cystinuria also excrete more than the normal amount of cystine, but the amount is not large, and these individuals only rarely form stones.

✓ Few of the aspects of cystinuria now remain unknown. Perhaps the major deficiency is proof that the two hereditary types, the recessive and incompletely recessive forms of the disease, are caused by allelic genes. But much remains to be done on the practical side in the recognition and treatment of cystinuric patients. The principles are well established and if effectively utilized could probably prevent calculus formation and its complications in most homozygotes.

This work was supported in part by grant AT(30-1) J01 from the U.S. Atomic Energy Commission and by grant A-567 from the Public Health Service.

There is much to be learned from the multitudinous research efforts on cystinuria in the past. The approach to be employed in this chapter is historical in order that from a vantage point of contemporary concepts the tortuous development of knowledge of the disease can be viewed in illuminating perspective.

## EARLY HISTORY AND DEFINITION

### *Initial Recognition*

Cystine and cystine stones were recognized long before cystinuria. Indeed the cystine with which many studies began was provided by the

Fig 42.1 Cystine tones from bladder (left 50.2 gm) from kidney (middle) and from ureter (right 40.7 gm) of patients originally reported by Vornor [5]. Although their appearance may be distinctive many such stones cannot be identified without chemical analysis (By permission of A. Renand, [6]).

patients themselves upon whom the supply of this essential material was dependent for nearly 100 years. In 1904 [2] and even in 1936 [8] cystine metabolism was tested by giving to an individual cystine from a stone which he had formed.

Wollaston, who 13 years earlier had described five different types of urinary calculi and demonstrated that extrusions from gouty tophi were identical with one of these, added a sixth type in a report to the Royal Society of London in 1810. On Cystic Oxide, a New Species of Urinary Calculus [4] (see Fig 42.1). Two examples of bladder stones had come into his hands. Wollaston considered the substance to be an oxide because of its tendency to unite with both acids and alkalis. Because of its occurrence in the bladder (Greek *kystis*) he gave it the name *cystic oxide*.

The name became a focus in the first debates about the new disease. Stones do develop in the bladder in cystinuria [5] especially in young

people. It was assumed that cystine stones were, therefore, formed by the bladder until in 1818 Marcet found three patients (two at autopsy) with renal stones of cystine. Berzelius observed that the substance was not an oxide and suggested the name *cystin*. Garrod observed in his third Croonian lecture [1] of this new name which has since been universally adopted. Civiale wrote in 1838, that although it corrected an error of chemistry, it perpetuated an error of physiology, for cystine is excreted by the kidneys and does not have its origin in the bladder.

Fig. 42-2 Typical microscopic hexagonal plates of cystine in sediment of cystinuric urine. Angles are each very nearly  $120^\circ$  despite irregular shape. (By permission of J. Renander [5].)

The renal origin of cystine was established when Prout in 1820 and Strohmeyer in 1824 (cited in [3]) recognized the same hexagonal platelets of cystine in the urinary sediment which Wollaston had formed from dissolved stones. The identification of these crystals through a microscope has remained until recent times the primary means of diagnosis of cystinuria (Fig. 42-2). The collection and weighing of these crystals was first done in 1855 by Toel (cited in [5]) who found a cystine excretion of 1.33 to 1.50 gm per day in a cystinuric patient. This procedure also became the basic method for the study of cystine metabolism until it was replaced after 1900 by Folin's urinary sulfur fractionations.

The slowly accumulating information from sporadic cases of cystinuria was harvested and first given form by Niemann in 1876 [6]. He tabulated in chronologic order and discussed in addition to his own patient, 52 cases which he found in the medical literature.

### *Diagnostic Criteria*

Nearly all the cases in Niemann's collection had been diagnosed on the basis of urinary stones of cystine although several had been recognized

by cystine crystalluria. He made careful drawings and crystallographic studies of these transparent shiny hexagonal leaflets seen with a microscope in the sediment of urine which had been allowed to stand for a few hours (Fig 42-3). The identification of cystine rested primarily upon

Fig 42-3 Niemann's engravings of crystal forms of cystine. Only microscopic hexagonal plates form spontaneously in urine (middle left). Recrystallization by evaporation after solution with ammonia gives plates and prisms or prismatic needles grouped above and to right of hexagonal plates. Recrystallization from acetic acid (below) rarely gives hexagonal plates but numerous prismatic forms. (From Niemann [6].)

Wollaston's criteria: the solubility of the crystals in ammonia and in solubility in acetic acid and when strong HCl was added to the dry crystals under the microscope the rapid growth of stellate clusters of delicate prisms consisting of the water-soluble cystine hydrochloride. Chemical analysis depended largely upon the "sulfur reaction": the

formation of a precipitate of lead sulfide when urine or a cystine solution was heated with KOH in the presence of lead acetate. He recognized that cystine could be present in the urine in abnormal amounts as indicated by the lead sulfide precipitate without the presence of stone or crystals.

By Niemann's criteria, a diagnosis of cystinuria suggested by a stone or crystals was confirmed by the identification of cystine through the strong sulfur reaction given by the solid material. Additional confirmatory evidence was the smell of hydrogen sulfide when the urine was allowed to stand long in hot weather, or the foul smell due to cadaverine and putrescine formed by bacterial action on the other amino acids now known to be present in these urines in abnormal amounts. Since the methods for detecting cystine depended upon precipitation from supersaturated solutions, it is not surprising that Niemann was cautious about excluding the diagnosis of cystinuria. He noted that cystine crystals are sometimes absent from the urine of individuals with a known cystine stone, that cystine crystalluria is sometimes present without stone, and that sometimes stones of other chemical composition are found in known cystinuric patients. The latter are now known to develop because of the urinary infections set up by the original stones.

### *Patterns of Occurrence*

Both males and females are affected with cystinuria, and males predominate. Niemann's collection of 53 patients was comprised of 38 males, 14 females, and 1 patient of unstated sex. A similar predominance of males, though slightly less marked, has characterized all subsequent collections of cases [7-9]. No significant sex difference, however, occurred in a later group of cases diagnosed by chemical examination [10].

Niemann believed that cystinuria is present from birth. The youngest patient seen up to that time was 2 years old. Frequencies of stone formation were similar in the successive decades of life [6], and no stones were reported after age 50. Since then a cystine stone has been passed spontaneously by a child of 9 months [11], and several cases are now on record of stone formation in older persons, including a woman of 87 [12]. In one patient stone formation occurred at age 42 and recurred at age 81 [13].

Niemann commented on the familial disposition of cystinuria. The fourth and fifth cases of Marcet (cited by Niemann) in 1818 were two brothers about 30 years old. Four other instances in which two siblings were affected had been reported, and in one of these the mother had also excreted abnormal amounts of cystine but did not have stones or crystalluria. It is interesting that the brother of Niemann's patient, who might well have had the same genotype, excreted abnormal amounts of cystine by chemical test; the mother and maternal uncle of the patient were normal in this regard.

### Possible Causes

His large collection of cases put Niemann on firm ground to evaluate the alleged constitutional or environmental causes of the disease. There was no association with occupation, social standing, housing, or nutrition or with scrofula, anemia, or rheumatism.

In 1868 Marowsky [14] from observations on a patient with cystinuria who also had chronic acholia and liver disease theorized that cystinuria is caused by liver disease. He believed that in cystinuria the usual taurine-secreting activity of the liver is suppressed and replaced by vicarious secretion of the sulfur-containing taurine through the kidney in the form of cystine. Niemann, however, found no evidence for the appearance in the urine of other fragments of the bile acids, and Lewis [16] later cited analyses showing no deficiency of taurocholic acid in the bile of cystinuric patients.

Niemann revamped Marowsky's hypothesis into the form later to be known as an arrest of metabolism—a concept from which Garrod developed his fertile idea of the inborn errors of metabolism. Instead of taurine's being converted to cystine as Marowsky implied, the formulas of the substance as then known

indicated to Niemann the reverse relation (the correct formulation does not alter this conclusion) that taurine is the natural oxidation product of cystine. His own measurements disclosed a low sulfate excretion in cystinuria. He failed to add the now obvious suggestion that a failure of cystine oxidation would cause the low urinary sulfate, but the pathway of cystine oxidation through taurine to sulfate was not yet known.

### Treatment

No treatment was used for Niemann's patient [6]. He reviewed earlier attempts at treatment and suggested that alkalinization of the urine might dissolve the cystine. Magendie is credited with the same suggestion, plus restriction of protein (cited in [5]). On one occasion Niemann's patient excreted an alkaline urine containing cystine crystals. This observation, in addition to the fear of precipitating phosphate with alkali and so enlarging the stones already present, restrained him from trying alkali therapy. Only surgical treatment was offered when necessary, and that sometimes tardily by modern standards.

### *Definitions*

Niemann's success in defining cystinuria, achieved largely by the use of logic to divest the known cases of their adventitious trappings, can be measured by comparing the conclusions with the definition of cystinuria written in 1955 by Dent and Senior [16]

It is a condition presumed to be present from birth and characterized by the excretion in the urine of large quantities of cystine (in the adult about 1 gm in 24 hours) lysine arginine and ornithine. The condition is often present in the patient's siblings and may result in the formation of stones composed almost entirely of cystine. Apart from the possibility of kidney damage and the other complications resulting from stone formation, the patients enjoy good health and are clinically indistinguishable from normal.

Niemann's definition agrees with this modern one in every detail, with the exception only of the abnormal amounts of lysine, arginine, and ornithine in the urine of these patients.

## CLINICAL AND BIOCHEMICAL NATURE OF CYSTINURIA

### *Clinical Reports*

After Niemann's review little could be added of clinical importance except validation of his definition of the disease until additional understanding was available. This was long in coming. Ebstein [17] 8 years later added 10 cases, and in 1900 Simon [18] brought the total to 103 cases and added 4 of his own and 1 from the Norwegian literature. One of his cases was a Negro, the only one reported to have cystinuria. These cases and others have been repeatedly reviewed [7, 19-21]. Sum Schick counted 180 cases by 1929 [22]. In the 10-year period between 1921 and 1932 Lewis [16] counted 71 newly reported cases. Morrison [11] listed 75 cases studied radiographically between 1920 and 1940. Renander's estimate that published cases by 1940 only slightly exceeded 200 was conservative [2].

Some cases have been of unusual interest. Southam [23] removed a cystine stone from a woman who 14 years postoperatively still excreted cystine. The mother of this patient had been operated on 24 years earlier by Southam's father also for cystine stone and she continued to excrete cystine for 8 years. The chronicity of the disease was further documented by a metabolic study in 1923 by Looney, Berglund, and Graves [24] of a patient studied 17 years earlier by Alsberg and Folin [25].

A dignified rivalry to report the largest stone can be discerned in the clinical literature. Chaos governed the contest since the participants frequently confused weights in grams with grains. The record, attested by an independent weighing 27 years later when the stone reposed in the Museum of the Royal College of Surgeons in England, was long held

by a vesical calculus weighing 68.04 gm and described by Harrison in 1849 [26] Lank found a stone of 86 gm in 1912 [21] Ancherson in 1914 removed from the bladder of a Norwegian male a cystine stone weighing 102.5 gm the largest that has ever been reported [27]

### Confusion with Cystinosis

A most notable confusion about the clinical nature of cystinuria was introduced by Abderhalden's description in 1903 of another disease of cystine metabolism [28]. Although Abderhalden called the new disease *familial cystine diathesis* the majority of medical writers up to the present time have considered it to be a manifestation of the same hereditary disturbance as cystinuria. After the next cases were described in 1926 by Lignac Leiden [29] it was also called *cystinosis* *cystine storage disease* and *Lignac-de Toni Fanconi syndrome* (see Chap 37). The first patient was seen only after death at age 21 months. The internal organs were potted with crystalline deposits of cystine. Abderhalden demonstrated abnormal amounts of cystine in the urine of two siblings the father (9.2 mg per 100 ml) and the grandfather (14.0 mg per 100 ml) of his patient. A reason for additional confusion was that Lignac's first case had ureteral and renal cystine stones (1926) a unique finding in any condition except cystinuria. The typical findings of cystinosis all of which distinguish it from cystinuria are retarded growth and development, rickets and osteomalacia, low serum phosphorus, glycosuria, generalized aminoaciduria of 10 or more amino acids among which cystine is usually not prominent, very rare formation of cystine stones, the presence of cystine crystals in the tissues of children but not adults with the disease [30] and its frequently fatal termination.

### BIOCHEMISTRY OF CYSTINE

A more precise definition of cystinuria was dependent upon knowledge of the chemical nature of cystine and of its metabolism. It would seem that both these aspects were well on the way to solution by 1900. Morner in 1899 [31] had discovered cystine in protein and found hydrolyzed hair to be an unusually rich source. The correct chemical formulas of cystine (II) and its reduced form cysteine (I) were established in 1902 by Friedman [32]

Chemical methods to measure urinary neutral sulfur (largely cystine) and organic sulfate were developed. The first balance studies on the sulfur

metabolism of a cystinuric person were reported in 1903 by Alsberg and Folin [2a]

Loewy and Neuberg [2] reported in 1904 that hair and stone cystine are metabolized differently and are different chemical substances. Alsberg and Folin [2a] promptly reported their own and other evidence against this conclusion. They were unable to verify such a difference (which hinged on a difference of crystal form), but as late as 1927 after the analysis of the 78 gm of stones from Tennant's patient [33] this error was repeated [34]. There was further confusion when it was observed that an increase in food protein produced an increase of cystine in the urine but when the food protein was hydrolyzed outside the body and the isolated cystine was given to the patient, that cystine was oxidized to sulfate. Cystine itself even cystine isolated from the patient's own urine [3a] caused no extra cystine to be excreted. Garrod [30] expressed the pessimism of the time when he wrote

The study of the metabolic peculiarities of cystinurics has yielded results which are very difficult of explanation and the more the problem is investigated the more remote seem to be the chances of its satisfactory elucidation. Thus in every case tested except that of Loewy and Neuberg in which cystine has been given by mouth it has been completely destroyed although the patients were all the time excreting cystine as such.

During the same period other observations were made from which the modern understanding of cystinuria could have been deduced. But like a hank of string with the key loop in sight, several pulls at other loops resulted in a snarl which took nearly 50 years to untangle.

#### CYSTINURIA AS AN 'INBORN ERROR OF METABOLISM'

Garrod announced his brilliant concept of the inborn errors of metabolism at the height of the confusion about cystine metabolism [1]. According to Garrod's thesis a hereditary condition characterized by the accumulation of an abnormal metabolite resulted from the hereditary lack of an enzyme that normally removes that metabolite. Here was an illuminating way to regard the accumulation of cystine, which in a normal individual is oxidized to sulfate. Cystinuria was included as one of the inborn errors of metabolism. This helped to obscure for a generation that a supposedly degradative enzyme in cystinuric subjects was in fact not missing. In both normal and cystinuric subjects cystine administered orally as such was oxidized and excreted as sulfate. The defect in cystinuria was manifested only if some precursor of cystine such as protein was fed. Garrod was not unaware of this paradox but he contented himself with the explanation that the metabolic error was partial and incomplete and that the contradiction would be resolved when more was known of the intermediary steps of sulfur metabolism.

There was ample evidence of the hereditary nature of cystinuria. Pfeiffer [37] reported four cystinuric children of parents who were first cousins. Cohn [38] described a family with a cystinuric mother, a normal father and 10 children. Six of the children were cystinuric, 2 definitely not and 2 untested. Two of the children were twins, both cystinuric. Identical twins, both with the disease, who also developed stones almost simultaneously, were later described by Kretschmer [7] and in another instance by Harris and Warren [39]. Garrod saw that this pattern was *meaningful*: homozygotes for a rare recessive gene would usually occur among siblings, rarely in other generations of the same family, and more commonly in families where a consanguineous marriage improved the chances that both parents would possess the rare gene. He did note, however, that there was a greater frequency of direct transmission of cystinuria from parent to child than was met in connection with the other metabolic errors he described (i.e. albinism, alcaptonuria and pentosuria). Fifty years later the recognition of a dominant form manifesting cystinuria in the heterozygote confirmed his impression [10].

#### METABOLISM OF CYSTINE

In 1935 the biochemist Brand and the urologist Cahill, with two young cystinuric patients, began to elucidate the metabolic pathway of the sulfur-containing amino acids by feeding experiments. The erroneous assumption of a block in cystine metabolism was useful. The identification of cystine precursors was as well served by the renal leakage of the extra cystine as it would have been by the supposed metabolic block. The new sulfur-containing amino acid, methionine, was promptly identified as a cystine precursor [40]. Proteins with high methionine content produced greater cystine excretion than proteins with low methionine content. The cystine in the protein was oxidized to sulfate [41]. This identification of methionine, and not cystine, as the principal dietary source of urinary cystine was confirmed by Lewis [3] and partially resolved the paradox described earlier. The subjects of Brand's experiments formed extra cystine from cysteine and from homocysteine but not from cystine or homocystine [42]. Brand postulated that cysteine is a product of the catabolism of methionine and that the error in cystinuria is a failure of the proper utilization of cysteine, not a failure of cystine metabolism. The final results clearly indicated a pathway of metabolism of sulfur-containing amino acids with the surprising sequence of reactions shown in Fig. 42-4 [40].

The excretion of cysteine as cystine by cystinuric patients and oxidation of cystine by both normal and cystinuric persons was in accord with what was known. The reaction, difficult to believe, was the shortening of the carbon chain in the conversion of the  $\gamma$  thio compound, homocysteine, to the  $\beta$  thio compound, cysteine. Lewis confirmed the essential

findings for the scheme of Fig 42-4, but he refused to accept the same conclusion

Brand's scheme [43] was confirmed in detail by studies from du Vig neaud's laboratory  $S^{35}$  labeled methionine gave rise to labeled cystine but  $C^{14}$ -labeled methionine did not [44] The shortening of the carbon chain occurs by transfer of the sulfur from the four-carbon compound homocysteine, to a different three carbon compound, serine, to form cysteine made up of the original sulfur but with new carbon atoms The intermediate of this interchange is cystathionine, a combination of both homocysteine and serine in one molecule This compound, too was later shown to give rise to cystine [45]

Fig 42-4 Pathway of metabolism of sulfur amino acids established in cystinuric patients by feeding experiments (From Brand et al [40]) Cystathionine was discovered later

After the pathway of sulfur amino acid metabolism in man was delineated by Brand through his studies of a patient with cystinuria a similar pathway (in reverse direction leading to methionine) was proved for *Neurospora* by the use of several mutants of this species [46]

The studies of Brand and his group still fell short of a full explanation of the disease The enzymic apparatus for cystine degradation by the cystinuric patient is obviously intact since cystine given as such is excreted as sulfate Any amount given orally can be oxidized by the liver but if cystine or cysteine is given parenterally to dogs or rabbits [47] or to a cystinuric patient [48] it is excreted by the kidney as cystine Failure of tubular resorption was later implicated quite directly by the fact that the level of cystine in the blood of cystinuric patients is not elevated [49] This eliminated the possibility of a renal overflow mechanism although it was apparently not appreciated by the authors at the time The meaning was not lost to all however for in 1934 Rabinowitch suggested that the mechanism of cystinuria is analogous to that of glycosuria

in renal glycosuria (which he thought was a result of an undue 'permeability' of the kidney [50]) There was left unexplained then only why the kidneys are presented with a greater load of cystine for excretion when a precursor is fed than when cystine is fed as such this question has still not been answered [51]

### AMINOACIDURIA OF CISTINURIA

An earlier series of experiments might have led to the recognition of the other amino acids (lysine arginine and ornithine) that are present in abnormal amounts in cystinuric urine

Ellinger [52] in 1898 found that bacteria would decarboxylate lysine and ornithine to form the foul smelling ptomaines or diamines cadaverine and putrescine. These substances had been isolated from the urine of many [18, 20] but not all cystinuric patients. The original patient studied in 1889 [53, 54] had cystitis and successive investigators over several years found the amounts of diamines increasing in pace with her urinary infection [55]. Recently Harris et al [10] reported a cystinuric patient who was exceptional among their patients in excreting no lysine. Upon closer examination they found a urinary tract infection and further analysis of the urine revealed the missing lysine present as cadaverine.

It seems now almost inconceivable that the work of Alsberg and Folin in 1905 [25] and its extension by Wolf and Shaffer in 1908 [48] did not quickly solve the problem of cystinuria. Alsberg and Folin tested the theory of defective hydrolysis of dietary protein by measuring the 'undetermined nitrogen' fraction of urine i.e. that part of the total

findings for the scheme of Fig 42-4, but he refused to accept the same conclusion

Brand's scheme [43] was confirmed in detail by studies from du Vigneaud's laboratory  $S^{35}$  labeled methionine gave rise to labeled cystine, but  $C^{14}$ -labeled methionine did not [44] The shortening of the carbon chain occurs by transfer of the sulfur from the four carbon compound, homocysteine to a different three carbon compound, serine to form cysteine made up of the original sulfur but with new carbon atoms The intermediate of this interchange is cystathionine, a combination of both homocysteine and serine in one molecule This compound too, was later shown to give rise to cystine [40]

Fig 42-4 Pathway of metabolism of sulfur amino acids established in cystinuric patients by feeding experiments (from Brand et al [40]) Cystathionine was discovered later

After the pathway of sulfur amino acid metabolism in man was delineated by Brand through his studies of a patient with cystinuria, a similar pathway (in reverse direction leading to methionine) was proved for *Neurospora* by the use of several mutants of this species [46]

The studies of Brand and his group still fell short of a full explanation of the disease The enzymic apparatus for cystine degradation by the cystinuric patient is obviously intact since cystine given as such is excreted as sulfate Any amount given orally can be oxidized by the liver but if cystine or cysteine is given parenterally to dogs or rabbits [47] or to a cystinuric patient [48] it is excreted by the kidney as cystine Failure of tubular resorption was later implicated quite directly by the fact that the level of cystine in the blood of cystinuric patients is not elevated [49] This eliminated the possibility of a renal overflow mechanism although it was apparently not appreciated by the authors at the time The meaning was not lost to all however for in 1934 Rabinowitch suggested that the mechanism of cystinuria is analogous to that of glycosuria

The project languished and the dogs were dispersed sometime before Brand's death in 1953, and before the new concept of the renal tubular mechanism in human cystinuria could be tested on cystinuric dogs. Metabolic studies nearly duplicated the findings from contemporaneous human studies. Cystine accounted for 13 to 17 per cent of the total urinary sulfur in the cystinuric dogs [62-64] compared with about 20

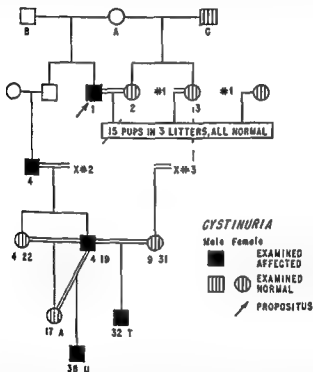

Fig 42-5 Known pedigree information of cystinuria in the Herrers. Original breeding system was retained. Litters were undoubtedly larger. A total of more than 300 descendants of dogs 1 and 4 were tested and 1 cystinuric animal, all males, was found. (From Brand et al [62] and W E Hess and M A Sullivan [63].)

to 30 per cent in the human being with cystinuria [3]. Extra cystine was excreted when extra protein, methionine or cysteine was fed. The feeding of cystine did not result in extra cystine excretion [65].

It remains to be shown whether the same discrete renal transport system under hereditary control is affected in the cystinuria of both men and dogs. It was in normal dogs that the competition between arginine and lysine for renal tubular excretion was first demonstrated [66]. This finding was initially the basis for the belief that the excretion of the several amino acids in man could be due to a deficiency of a single renal

nitrogen left after subtraction of that determined independently in urea ammonia creatinine, uric acid and cystine. Their patient excreted abnormally large amounts of the undetermined nitrogenous substances as well as cystine during starvation. They concluded that these were produced by 'endogenous metabolism' but both fractions were also increased in proportion to the protein in the diet and therefore were also produced by 'exogenous metabolism'.

Four years later Wolf and Shaffer [48] confirmed the results of Alsberg and Iolin in detail and emphasized that there is an abnormal excretion of 'undetermined nitrogen' in cystinuria and that this is at least in part due to other amino acids. Somehow, this was forgotten. Later isolations of crystalline lysine derivatives from cystinuric urine by Ackermann and Kutscher in 1911 [50a] and by Hoppe-Seyler in 1933 [50] passed almost unnoticed and the observations were not corroborated. Kutscher obtained amounts equivalent to 0.1 gm lysine per liter of urine which was grossly more than could be present in normal urine. The discovery and identification of three other amino acids besides cystine in cystinuric urine 40 years later was a major forward step in the understanding of this disease.

#### CYSTINURIA IN ANIMALS

The sporadic occurrence of urinary cystine stones in dogs was reported in 1823 by Iassaigne [57] in 1861 by Gross [58] and by Lentz in a male dachshund in 1921 [59]. The stone was always recognized after the death of the animal and no metabolic studies were made. The tendency to form cystine stones was not associated with a single breed, as is the frequent development of urate stones in the Dalmatian coach hound. In 1935 Morris [60] found that an Irish terrier suffering from urinary retention had cystine crystalluria. At operation several vesicular and urethral calculi of cystine were successfully removed [60]. Brand and Cahill joined the study, made the necessary chemical measurements to identify the disease and arranged a breeding program to investigate the genetics of the condition.

Through the American Kennel Club registrations of the sire and dam of the first cystinuric dog, four related dogs were found to begin a breeding program. One, a cousin of the proband, also had cystinuria [61]. Twenty-five unrelated animals of the same breed were not cystinuric. Three hundred dogs of the cystinuric strain were raised and 12 cystinuric animals were identified. All affected animals were males [61, 62]. The original cystinuric male produced litters with an unrelated female and with two half sisters. None of the 15 pups was cystinuric [64]. No genetic analysis of the results was ever made, but the few published pedigrees resembled, or at least did not exclude, sex-linked inheritance [62, 63], one quite different from the recessive pattern seen in man (Fig. 42.5).

excretions about ten times the normal level [76] Equally powerful and even more convenient methods of amino acid analysis soon confirmed these new abnormalities Column chromatography of the urinary amino acids in six cystinuric patients all with histories of cystine stone formation showed that a definite pattern of aminoaciduria was characteristic of this disease [77] In addition to the cystine lysine and arginine already identified ornithine was also found in abnormal amounts The amounts of the remaining amino acids were not different from normal

The first explanation of the large amounts of new amino acids found in the urine of cystinuria was progressive renal damage producing first the leakage of these few amino acids and later perhaps the generalized aminoaciduria seen in the Fanconi syndrome [76] However long clinical experience belied this A nonspecific renal damage would not show such specific leakages

### *Renal Physiology and Aminoaciduria*

The possibility that a discrete renal tubular transport mechanism with enzyme like specificity could be defective in cystinuria and permit the specific aminoaciduria was first appreciated in 1951 It was known that arginine and lysine compete for the same tubular reabsorptive mechanism in the kidney of the dog each lowering the  $T_m$  of the other [60] Dent and Rose [78] suggested that the reabsorptive mechanism was missing in cystinuria The first evidence to substantiate this was an elaboration of an old finding by Brown and Lewis in 1937 [49] that the concentration of cystine in the blood of a cystinuric patient is not elevated In 10 normal and 9 cystinuric individuals the concentration of cystine in the plasma averaged 0.82 and 0.69 mg per 100 ml respectively [9] It was argued that if cystinuria was the result of a renal defect the plasma level would be normal or low as it appeared to be but that if it was the result of a blocked cystine metabolism the plasma level should be elevated Evidence was presented that the levels in blood are not above normal for the other amino acids also excreted in cystinuria [80] Stein and Moore [81] established that high plasma concentrations of amino acids could not account for the excretions since the levels of lysine and ornithine were normal and of cystine and arginine low in their patient

The crucial evidence for a specific renal mechanism was obtained from the renal clearance of the amino acids In a classic study by Dent Senior and Walshe [81] cystine clearance in normal individuals was of the order of 4 ml per min whereas in two cystinuric patients (both with considerable renal damage from stone formation and therefore probably with reduced glomerular filtration rates) the cystine clearances were approximately 100 ml per min i.e. they approached the glomerular filtration rate Moreover in a person known to be heterozygous for cystinuria, a definitely elevated cystine clearance (14 ml per min) was found

transport system. Opportunities to make observations on such dogs are apparently not rare. Krabbe [66] reported that 3 per cent of the urinary calculi removed from dogs in Holland and Denmark are cystine. In England they accounted for 18 per cent, according to White [67] and were the stones which most commonly caused urethral impaction. Crane and Turner [68] found cystine and lysine predominating in the urine of a Labrador retriever who had two episodes of cystine vesical calculi with urethral impaction. No abnormal quantities of arginine or ornithine were found. Study of the plasma was inconclusive. This is the urinary pattern expected in the heterozygous form of incompletely recessive cystinuria in man (see below).

A second species of animal with cystinuria is the blotched genet, a wild cat from Kenya. In a survey by paper chromatography of the amino acids excreted by different animals at a zoo, Datta and Harris [69] found that every blotched genet was cystinuric. The condition was present in a number of unrelated members of the species, so it was not just a familial condition *within* the species, but a species characteristic.

The cystinuria of the Kenya genet differs from that in man in that high concentrations of other amino acids are not excreted. Dent and Senior [16] also established that the cystinuria occurred by a renal mechanism, i.e., a deficiency of tubular reabsorption. Strangely enough, the concentration of cystine in the genet urine is 1 to 3 mg per ml *in true solution*, that is, about four times its solubility in human urine. Yet the genets do not form urinary cystine stones. The failure of cystine to precipitate from these urines raises again the possibility of a cystine-containing complex existing in cystinuric urines of man [40, 70, 71] and dog [63], although the existence of such a complex has been emphatically denied [3]. No additional cystine, lysine, or arginine is found in human cystinuric urine after hydrolysis [72]. The early belief in such a cystine complex may have arisen from a theory that when cystine is absorbed as a peptide because of faulty digestion, it escapes oxidation and produces cystinuria [73]. No stable complex of cystine was found in genet urine. The unusually high urea concentration of 10 to 20 gm per 100 ml in genet urine, and the presence of other salts and amino acids [74] might affect the solubility of cystine.

Recently cystine urinary stones have been discovered in a third animal species, the mink [70].

#### RENAL TIBULE AND CYSTINURIA

##### *Pattern of Aminoaciduria*

In 1947 microbiologic determinations of the individual amino acids in the urine of a cystinuric girl (compared with analyses in seven female controls) showed a high cystine excretion, but also arginine and lysine

excretions about ten times the normal level [76]. Equally powerful and even more convenient methods of amino acid analysis soon confirmed these new abnormalities. Column chromatography of the urinary amino acids in six cystinuric patients, all with histories of cystine stone formation showed that a definite pattern of aminoaciduria was characteristic of this disease [77]. In addition to the cystine lysine and arginine already identified ornithine was also found in abnormal amounts. The amounts of the remaining amino acids were not different from normal.

The first explanation of the large amounts of new amino acids found in the urine of cystinuria was progressive renal damage producing first the leakage of these few amino acids and later perhaps the generalized aminoaciduria seen in the Fanconi syndrome [76]. However, long clinical experience belied this. A nonspecific renal damage would not show such specific leakages.

### *Renal Physiology and Aminoaciduria*

The possibility that a discrete renal tubular transport mechanism with enzyme-like specificity could be defective in cystinuria and permit the specific aminoaciduria was first appreciated in 1951. It was known that arginine and lysine compete for the same tubular reabsorptive mechanism in the kidney of the dog each lowering the  $T_m$  of the other [60]. Dent and Rose [78] suggested that the reabsorptive mechanism was missing in cystinuria. The first evidence to substantiate this was an elaboration of an old finding by Brown and Lewis in 1937 [49] that the concentration of cystine in the blood of a cystinuric patient is not elevated. In 10 normal and 9 cystinuric individuals the concentration of cystine in the plasma averaged 0.82 and 0.69 mg per 100 ml, respectively [49]. It was argued that if cystinuria was the result of a renal defect the plasma level would be normal or low as it appeared to be but that if it was the result of a blocked cystine metabolism the plasma level should be elevated. Evidence was presented that the levels in blood are not above normal for the other amino acids also excreted in cystinuria [80]. Stein and Moore [81] established that high plasma concentrations of amino acids could not account for the excretions since the levels of lysine and ornithine were normal and of cystine and arginine low in their patient.

The crucial evidence for a specific renal mechanism was obtained from the renal clearance of the amino acids. In a classic study by Dent Senior and Walsh [41] cystine clearance in normal individuals was of the order of 4 ml per min whereas in two cystinuric patients (both with considerable renal damage from stone formation and therefore probably with reduced glomerular filtration rates) the cystine clearances were approximately 100 ml per min i.e. they approached the glomerular filtration rate. Moreover in a person known to be heterozygous for cystinuria, a definitely elevated cystine clearance (14 ml per min) was found.

Elevated renal clearances in cystinuric patients of cystine, arginine, ornithine, and lysine were then demonstrated by Robson and Rose [82]. The clearances of cystine, arginine, and ornithine were not further increased by the rapid intravenous infusion of 5 gm of L-lysine, because the clearances were already near the glomerular filtration rate. In normal individuals and heterozygotes lysine caused transient increases in the clearances of the three other amino acids, and only of the three that are excreted in cystinuria. This is analogous to competitive inhibition of an enzyme.

Doolan, Harper, Hutchin, and Alpen [72] also established that the plasma level of lysine was lower than that of normal subjects in four cystinuric patients (2.4 compared with 3.2 mg per 100 ml) and that extra lysine (and arginine) was cleared at a rate similar to that of inulin, i.e. without reabsorption. The excretions observed were much too large for leakage of filtrate past a few inactive nephrons. A specific defect in renal tubular reabsorption was therefore established.

Cystinuria may then be defined as a hereditary inactivity of a specific renal tubular transport system which normally combines with and reabsorbs the several related dibasic amino acids. The inactivity could result from an absence or defect of a specific enzyme-like combining substance in the tubular cells. It has been suggested that the enzyme-like combining substance of the transport system fits substrates with two suitably separated amino groups, and that this is the structural basis for the common transport of these four dibasic amino acids (see Effect of Genotype on Renal Tubular Transport below). Within the group the affinity for the combining substance ( $K_m$  of an enzyme) is less for cystine and lysine than for arginine and ornithine, as the genetic studies have indicated (see below).

With the demonstration that a specific renal transport system for certain amino acids is lacking in cystinuria, it became possible to ask if this same transport system is operative in other tissues besides the kidney. The absorption of amino acids by the intestine and their concentration into cells, for example, occurs with transport systems apparently similar to those of the kidney tubule. There is no positive indication of interference with such systems in cystinuria except in the kidney. Only direct tests could rule out such a possibility, however, and one such observation has been recorded. Leukocytes of normal and cystinuric individuals take up cystine and lysine equally efficiently. There is no mutual inhibition of uptake by the cells between these two amino acids [83].

#### INCIDENCE OF CHEMICAL AND CLINICAL CYSTINURIA

Most surveys [22-84] of which Morner's is the most complete [85] have generally agreed that about 1 per cent of all urinary calculi are

cystine There are no reliable estimates of the incidence of urinary calculi in the general population with which the absolute incidence of cystinuria can be correlated

The incidence of cystine crystalluria has been reported to be 1 case in 15 000 [18] one in 20 000 [86] and four in 35 000 [87] The over all incidence is therefore approximately one in 10 000 urine specimens This is possibly higher than in the general population since undoubtedly only selected (e.g. hospitalized) populations were tested

The apparent incidence of cystinuria depends largely on the prevailing interest in the disease Morner's experience in Sweden illustrates this The first case was seen in Sweden in 1870 and the second in 1901 Morner [85] reported 6 seen during the period 1901 to 1920 Sixteen additional cases only 4 without stones were observed in the next 5 years [9] The diagnostic criteria had not changed from the earliest time By 1936 Morner had found a total of 36 cases of cystinuria in the generation of the Swedish population living since 1901 Renander [6] then surveyed independently all hospitals in the country and succeeded in finding only one additional case These studies approach a complete ascertainment of cystinuria in a mean population of 6 million and give a (probably low) incidence of roughly 1/200 000

Between 1929 and 1931 Lewis examined the urine of 10 534 University of Michigan students with the cyanide nitroprusside test and when that was positive by the more specific Sullivan test for cystine [8] The normal excretion of cystine is in the range of 40 to 80 mg per day [88] and approximately the same amount per gram of urinary creatinine [39] It has been estimated that Lewis's cyanide nitroprusside test would be distinctly positive with at least 100 to 125 mg cystine per gram of creatinine [39] Lewis discovered 18 individuals or 1 in 600 who consistently excreted cystine Eleven of these were studied in more detail and all showed an abnormally elevated urinary organic sulfur fraction Four showed repeated cystine crystalluria (4 in 10 000) Earlier estimates of the incidence of cystine crystalluria were less than one fourth this high but they were based on single examinations for a condition known to occur only intermittently None of Lewis's subjects had ever had symptoms suggestive of renal stone or colic and only one gave a family history of such disease A sister of one of the individuals had formed a cystine stone but his parents and five other siblings did not excrete cystine The urine of 22 other individuals in the population studied gave weakly positive tests consistently or occasionally The total incidence of positive tests was 1 in 250 Those giving weakly positive tests had nearly normal sulfur partitions and were considered normal Malleon (cited in [39]) confirmed the high incidence of chemical cystinuria (1 in 250) with the finding of four positive urines from approximately 1000 students at University College London These urines contained 106 to 161 mg

cystine per gram of creatinine, and paper chromatography demonstrated in all an increased output of lysine as well as cystine

The finding of excess excretion of cystine by 1 in 250 people introduced a new entity, chemical cystinuria. An additional criterion besides cystine excretion was obviously necessary to identify the specific disease cystinuria in stoneless persons, and to distinguish it from other conditions which might cause chemical cystinuria. The specific aminoaciduria with four amino acids provided the criterion in the absence of stone formation. The high frequency of chemical cystinuria found an explanation in the frequency of heterozygotes that can be deduced from studies of the genetics of the disease as determined from the specific aminoaciduria.

Dent and Harris undertook a study of cystinuria in terms of the specific aminoaciduria [89]. The result was simply to redefine what has been called cystinuria as a specific hereditary condition characterized by the presence of the four amino acids in abnormal amounts and to prove that it is distinct from the inherited Fanconi syndrome and from Wilson's disease. Studies of the families of three individuals with the latter two diseases disclosed three other individuals with a general aminoaciduria and none with the specific cystine-arginine-lysine-ornithine type of aminoaciduria. The families of seven classical cystinuric patients, six of whom had stones, contained seven more individuals of the same specific type and none with generalized aminoaciduria. These findings directly disproved the idea that cystinuria is a stage in the development of the Fanconi syndrome [76].

#### PATTERNS OF INHERITANCE

The familial incidence of cystinuria among siblings was such that Garrod suggested its inheritance as a rare recessive trait. Even then, however, too many instances of direct transmission from parent to child were known and Garrod entertained the possibility that the condition might be dominant. An alternative explanation, that the gene is very common instead of rare, would also account for the presence of the disease in two successive generations. This explanation gained credence when it was known that chemical cystinuria is much more common than the incidence of stone formation.

From a consideration of the published pedigrees of cystinuria, complete except for those of Niemann [6], Kretschmer [7] and Morner [9, 90], Dent and Harris concluded that the available data were of little genetic value since only five families had been examined with chemical methods and in none of these was there information about the excretion of other amino acids. The data from the earlier studies simply reemphasized the mutually contradictory points made by Garrod: the frequency of parental consanguinity and of cases among siblings indicates that cystinuria is a rare homozygous recessive disease, whereas the presence of affected

individuals in three successive generations of the same family [91] almost certainly indicates that some patients are heterozygotes i.e. that the condition is sometimes dominant.

Analysis of the new family data collected by Dent and Harris did not resolve this problem. In two instances the parents of cystinuric patients were normal, so that the condition is not regularly manifested in heterozygotes. The occurrence of affected parent-child pairs in two of the seven families could be explained on the recessive hypothesis with a postulated high frequency of the gene in the population (one individual in 12 would be a heterozygote if Lewis's incidence of 1 in 600 represented the homozygous form). But if the gene is so common consanguinity would not be important for its expression. Yet even in this small series there was one consanguineous marriage. It was apparent that the genetics of cystinuria, half known for so long on the basis of the qualitative excretion of cystine, would yield fully only to a detailed quantitative study.

Quantitative studies by Harris and coworkers of the amino acid excretion in cystinuric families provided the answer. Measurements in 21 families [39] showed in some of the families the expected clear separation into cystinuric and normal individuals. In other families there was a continuous gradation from normal to extremely abnormal cystine excretion in the different individuals. It was evident that the disease appeared in two forms, separately inherited.

### *Recessive Cystinuria*

The first type, the more common of the two forms of cystinuria, appeared in families where all individuals excreted either normal or highly abnormal amounts of urinary cystine and no individuals had intermediary values. There was a sharp segregation for the property of cystine excretion and the family distribution was of the type expected if the cystinuria occurred in individuals homozygous for a rare recessive gene. The parents, who were apparently normal, were necessarily heterozygotes, but the one recessive abnormal gene which they possessed was not strong enough to create any noticeable effect on cystine excretion. Thus the defect appeared only among the homozygous offspring. Four instances of consanguinity in these families further supported this view. This type is called recessive cystinuria.

### *Incompletely Recessive Cystinuria*

In families of the second type, normal, intermediate and high values of cystine excretion were all found. The family distributions suggested that the individuals with moderately raised values of cystine excretion were heterozygotes. Those with high values, like the affected individuals in the recessive families, were homozygous for a rare gene. Because the character of the incompletely recessive gene in the second type of

family was strong enough to produce intermediary values in the heterozygotes, it was assumed that the individuals with normal cystine values did not possess the gene for cystinuria. Further quantitative studies of the other amino acids excreted made it clear that the earlier contradictory results had found their explanation in two different modes of inheritance of different degrees of the same renal defect.

### *Effect of Genotype on Renal Tubular Transport*

The variant forms of the disease originate in the inheritance of different degrees of the renal defect. This was clear from a study by Harris

Fig. 42.6 Cystine output of cystinuric subjects and their relatives ranged from 15 to 800 mg per gm creatinine. Stone formers were clustered among the high cystine excretors. (By permission of H. Harris and F. L. Warren [32].)

and coworkers of lysine and arginine excretions [92]. Their patients included 28 stone-forming cystinuric persons and 121 of their relatives. All degrees of cystinuria from 20 to 800 mg cystine per gram creatinine were found. There was stone formation only in individuals who excreted 250 mg cystine per gram creatinine or more. This was the level at which a saturating concentration of cystine in urine would be likely to occur (Fig. 42.6). The lysine excretion was regularly about twice that of cystine and paralleled the cystine excretion throughout all its gradations. Arginine and ornithine were not excreted in abnormal amounts until the cystine and lysine reabsorptions were seriously impaired. Only with a

Fig 4-7 Cystine and lysine contents of urine from a series of cystinuric patients and their relatives (By permission of H Harris and E B Robson [94])

Fig 4-8 Lysine to cystine content of urine from a series of cystinuric patients and their relatives (By permission of H Harris and E B Robson [94])

cystine excretion of 250 mg per gm creatinine or more did arginine and ornithine also appear in the urine in abnormal amounts. The amounts then increased proportionally with the excretion of higher amounts of cystine and lysine. These relationships, which held in families with both recessive and incompletely recessive cystinuria, are shown graphically in Figs. 42.7 and 42.8. Subsequent studies have indicated that the variations in the arginine to lysine ratio are genetically determined in the recessive homozygotes and may indicate still other variants of the disease [93, 94].

These genetic studies revealed a hierarchy of affinities of substances for a renal transport system, comparable to the affinities of substrates for an enzyme. Arginine and ornithine had high affinities and were preferentially reabsorbed by the tubular mechanism. Cystine and lysine affinities were lower and their reabsorption failed first. The genetically determined degrees of the renal defect, if partial, permitted the preferential reabsorption of arginine and ornithine, and if more complete, resulted in the renal loss of all four amino acids including cystine, in sufficient concentration for the latter to precipitate and form stones.

#### *Phenotypes and Genotypes and Incidence of Cystinuria*

The biochemical and genetic data of Harris et al. [39-92] were finally correlated in a definitive paper, 'Phenotypes and Genotypes in Cystinuria' [10]. A total of 29 families, each with at least one stone-forming cystinuric member, was reported. Two of these families could not be definitely categorized as to type from the data available, but in all families the homozygous individuals were indistinguishable. They excreted approximately the same highly abnormal amounts of the four amino acids and nearly all formed cystine stones. In 19 of the families the condition was recessive and no degree of abnormality was found except the extreme form in the homozygote. In 8 families the condition was incompletely recessive and the heterozygote showed moderately increased excretion of cystine and lysine without increased excretion of arginine or ornithine. Only in rare instances did the latter excrete sufficient cystine to form stones.

The simplest explanation of the two variant forms of cystinuria is that there are at least two mutant conditions of one gene. One would have a mild and the other a severe effect on the tubular reabsorption of the four amino acids in the heterozygous state. Genetic proof of this possibility must await identification of a homozygous cystinuric person, one of whose parents is the apparently normal heterozygote of the recessive type and the other a heterozygote of the incompletely recessive type of cystinuria. Families evidently of this kind are on record. Detailed chemical identification of the type of each individual in such a pedigree has not been made.

Implicit in the above figures of the relative frequency of the two types is the explanation of the rarity of cystine stone and the commonness of chemical cystinuria. The incidence of chemical cystinuria can be accepted at the maximal figure of 1 in 250 and all cases can be attributed to heterozygotes of the rare incompletely recessive form of cystinuria. Since the frequency of heterozygotes of a rare disease is approximately  $2\sqrt{\text{incidence}}$  of the homozygotes the incidence of incompletely recessive cystinuric homozygotes would be 1 in 250 000. Since recessive cystinuria has been found twice as often as the incompletely recessive type the incidence of cystinuria of both types would then be roughly 1 in 80 000. This is a reasonable figure between the maximum estimates based on crystalluria in selected cases and the ascertainment by Morner of the incidence in Sweden which set the minimal incidence at 1 in 200 000.

## DIAGNOSIS

A patient with cystine calculus may be seen at any age and at any stage of the familiar progression of renal or ureteral colic urinary tract obstruction hydronephrosis and secondary bacterial infection. Operative interferences and stone recurrences increase the risk of chronic pyelonephritis progressive renal insufficiency and finally uremia. Diagnosis depends upon chemical identification of cystine in the urine or the stone. The simple test for cystine in the urine should be performed routinely on all patients suspected of having urinary stones since the stones tend to recur and appropriate treatment may be most beneficial.

Cystine stones are about three times as dense to x rays as the poorly visualized urate stones and about equally as dense as the more common calcium magnesium and oxalate stones [9, 11]. There is nothing characteristic or diagnostic about the radiographic appearance.

### *Microscopic Crystalluria*

Microscopic examination of the urinary sediment for cystine crystals is a most useful diagnostic method. The incidence of cystine crystalluria in the population determined by this method is slightly greater than expected for the incidence of the homozygotes. Although the present tendency is to use chemical methods whenever possible it is clear that microscopic crystalluria in concentrated (morning) urines is a test sufficiently sensitive to identify the homozygotes. Since stone formation occurs only in (adult) individuals who excrete 0.4 gm or more cystine per day (2.0 mg per gm creatinine) [92] and no more than this amount dissolves in 1 liter urine at 37°C between pH 5 and 7 it follows that crystals should form when the volume of the 24 hr urine output of potential stone formers is 1 liter or less and the sample is allowed to

stand and cool for several hours before centrifugation. If crystals are sought in the relatively concentrated and acid morning urine, cystine crystals should be found in the sediment of urines from at least those cystinuric patients who might form stones. If a little glacial acetic acid is added (pH 4) and the urine refrigerated overnight, the test becomes even more reliable.

### *Chemical Tests for Cystine*

Although screening tests employing a simple determination of urinary  $\alpha$ -amino nitrogen promise to be of great value in cystinuria, the simple screening procedure for cystine used by Lewis [10] remains the basic clinical test and should be used more widely. The cyanide-nitroprusside reaction is negative with normal individuals, slightly positive with the raised amounts of cystine in urine of heterozygotes of the incompletely recessive disease, and strongly positive in urine of the homozygotes. Acetone and certain drugs can also give positive reactions.

To 5 ml urine add several drops concentrated ammonium hydroxide and 2 ml freshly prepared 5 per cent NaCN. Mix and wait 10 min for the reduction of cystine to cysteine. Add dropwise some freshly prepared 5 per cent sodium nitroprusside. A deep-purple color which fades gradually is a positive result for cystine.

The more specific Sullivan reaction can be used for confirmation. After reduction of cystine as above, add 1 ml freshly prepared 0.5 per cent 1,2-naphthaquinone-4-sodium sulfonate and mix. Add 5 ml of 20 per cent anhydrous  $\text{Na}_2\text{SO}_3$  dissolved in 0.5 N NaOH and mix. After 30 min the solution is reddish brown. One milliliter of 2 per cent  $\text{Na}_2\text{S}_2\text{O}_3$  dissolved in 0.5 N NaOH converts the color to a purer red.

The method of choice for quantitative cystine studies is polarography [51]; column chromatographic methods [81] are also good.

### *Identification of Heterozygotes and Homozygotes*

For any purposes other than the purely practical problem of clinical diagnosis, chemical identification of the specific aminoaciduria is essential. Paper chromatography will distinguish the generalized aminoacidurias of Fanconi's syndrome or Wilson's disease. Another common problem is the identification of the heterozygotes of the incompletely recessive form of cystinuria. The nature of the problem can be seen from the average values of three amino acids in the urine of normal and cystinuric individuals given in Table 42.1. The family pattern needed to indicate that the two types of cystinuria are allelomorphic should have the excretions of one parent like the controls (heterozygote-recessive type) and of one parent like the heterozygote of the incompletely recessive type and of one offspring like the homozygote. As already mentioned, quantitative cystine determinations will help in distinguishing these kinds of

individuals. The major distinction is the excretion of grossly abnormal amounts of arginine and ornithine in the homozygotes only. They also excrete high amounts of cystine and lysine. The presence of abnormal amounts of arginine and ornithine and the very high total  $\alpha$ -amino nitrogen is therefore characteristic of the homozygote. Moderate cystine and lysine excretion without these other characteristics and without generalized aminoaciduria is found in the heterozygotes of the incompletely recessive type.

## TREATMENT

Cystinuric patients enjoy excellent health and are long lived except for the complication of urinary stone formation in the homozygous individuals. The heterozygotes of the incompletely recessive form, who account for the vast majority of cystine excretors, rarely form stones and need no treatment unless their cystine excretion is over 200 mg per gm creatinine. No adverse effect is apparent from the quite considerable daily loss in the urine of the essential amino acids lysine and arginine. Subtle effects which might be seen only under stress and during unusual

TABLE 42-1 AVERAGE URINARY AMINO ACIDS

amino acid requirements have not been noticed. For example, the high lysine requirement for rebuilding hemoglobin after blood loss, or the high arginine supply reputedly necessary for growth of spermatozoa, might be met with difficulty by the cystinuric patient, but observations on these points have yet to be made. In one healthy 23-year-old cystinuric person, healing of a broken leg was delayed far beyond the usual time, but others have undergone major surgical procedures without difficulty. The specific aims of treatment should be to prevent initial and recurrent stone formation and, when dissolution is preferable to surgical intervention, to dissolve stones already formed. These aims appear to be attainable.

The characteristics which favor the successful treatment and prevention of cystine lithiasis also make it an ideal model of the study of the general mechanism of stone formation. Many factors of an inconstant

stand and cool for several hours before centrifugation. If crystals are sought in the relatively concentrated and acid morning urine, cystine crystals should be found in the sediment of urines from at least those cystinuric patients who might form stones. If a little glacial acetic acid is added (pH 4) and the urine refrigerated overnight, the test becomes even more reliable.

### *Chemical Tests for Cystine*

Although screening tests employing a simple determination of urinary  $\alpha$  amino nitrogen promise to be of great value in cystinuria, the simple screening procedure for cystine used by Lewis [10] remains the basic clinical test and should be used more widely. The cyanide nitroprusside reaction is negative with normal individuals, slightly positive with the raised amounts of cystine in urine of heterozygotes of the incompletely recessive disease, and strongly positive in urine of the homozygotes. The method of choice for quantitative cystine studies is polarography [51]. Column chromatographic methods [31] are also good.

### *Identification of Heterozygotes and Homozygotes*

For any purposes other than the purely practical problem of clinical diagnosis, chemical identification of the specific aminoaciduria is essential. Paper chromatography will distinguish the generalized aminoacidurias of I anconi syndrome or Wilson's disease. Another common problem is the identification of the heterozygotes of the incompletely recessive form of cystinuria. The nature of the problem can be seen from the average values of three amino acids in the urine of normal and cystinuric individuals given in Table 42.1. The family pattern needed to indicate that the two types of cystinuria are allelomorphic should have the excretions of one parent like the controls (heterozygote-recessive type) and of one offspring like the heterozygote of the incompletely recessive type and of one offspring like the homozygote. As already mentioned, quantitative cystine determinations will help in distinguishing these kinds of

### Solubility of Cystine in Urine

Major reliance must be placed upon efforts to increase the solubility of cystine in the urine and to increase the volume of urine. It was noticed as early as 1890 that cystine is more soluble in urine than in water. Blix [97] made a careful study of the increased solubility caused by increased pH and by mineral constituents, diffusible organic materials and colloidal substances. The various salts of urine tested individually or in combination increased the amount of cystine which would dissolve by about 50 per cent but Blix attributed the major effect to colloidal substances remaining in dialyzed urine which dissolved twice as much cystine as did water.

An elegant study of the solubilizing effect of NaCl and of glycine on cystine was published by Cohn, McNeekin and Blanchard [74]. The profound solvent action of either of these substances nearly doubled the solubility of cystine but effects were not additive. Dent and Senior [16] found no increased solubility by concentrations of urea up to 10 gm per 100 ml. This was suggested by the high solubility of cystine in the urea-rich urine of the Kenya genet [69]. NaCl, other amino acids and hippuric acid also failed to increase the solubility of cystine in urine. The only prospects of producing a clinically significant increase in cystine solubility in urine appear to depend upon pH and upon possible colloidal solubilizers [70] or complexes of cystine. There is no real evidence for the existence of a more soluble complex form of cystine but in view of the striking solubilities reported in genet urine the subject warrants further study.

There is an important effect of pH on the solubility of cystine in urine (Fig. 42-9). Unfortunately little of it is in the physiologic range. From pH 5 to 7 the increase in solubility is only from 0.31 gm to 11.40 gm per liter [16]. To obtain a significant effect the urine pH must be held near the maximum of alkalinity and must certainly be above pH 7.5. This is greater alkalinity than can be produced by a high vegetable and fruit diet alone. The clinical problem is comparable to that of preventing precipitation in the kidney of the early sulfonamide compounds. Sufficient clinical experience with intensive alkali therapy is available to warrant its use at least under hospital supervision even for dissolving stones. Carbonic anhydrase inhibitors like Diamox greatly simplify the production of an alkaline urine for limited periods. Intensive alkali therapy

Fig. 42-9 The solubility of cystine in urine at 37°C with different pH's (Redrawn from C. E. Dent and B. Senior [16]). Cystine is about half as soluble in water.

nature, such as diet infection and urinary tract abnormalities, may be concerned with the seeding, propagation, and placement of stones in the urinary tract. At the present time however, stone formation is best considered as due to simple precipitation from supersaturated solutions. It is probable that this mechanism is the one of primary importance in cystinuria even if not in other calculous diseases, since there is a close correlation between the amount of cystine excreted and the tendency to form stones. Most individuals who excrete sufficient cystine ultimately develop stones. Certainly the concentration of cystine in the urine is the single overwhelmingly important factor in the genesis of these stones. Crystallization can be minimized by reducing the cystine concentration either by reducing the amount or by increasing the urine volume, or by increasing the solubility of cystine.

### *Quantity of Cystine in Urine*

Only a small degree of control over the amount of cystine excreted can be expected. A variety of ingenious means have been tried without success to draw cystine off into metabolic bypaths [6, 96] but the only effective way of diminishing the amount of cystine excreted is by dietary protein restriction—a method advocated for as long as cystine has been identified as a constituent of protein. The fact that more cystine is excreted on high protein diets was not fully accepted despite positive proof [25] until the experiments of Brand et al [41]. This is because the effect of protein is small and the amount of cystine in urine merely a reflection of its blood concentration. The blood level is maintained from tissue as well as dietary sources, and surpluses can be metabolized. Only the methionine in the protein not the cystine significantly raises the blood level of cystine. Severe protein restriction will only cause weight loss and negative nitrogen balance which like fever will increase the breakdown of body protein and the excretion of cystine. Excess protein should be avoided but enough must be given to replace the essential amino acids continually lost in the urine in this disease.

It is possible that high protein diets were the usual fare of two unusual patients who regularly excreted about 3 gm cystine per day at least twice the amount usually found in cystinuria [96]. Fluid and alkali therapy were inadequate to prevent stone formation in these patients and dietary measures limiting methionine intake were successfully used to decrease cystine output to the point where other therapies controlled the crystallization. The diet used was only moderately low in protein, but the proteins were substantially of vegetable origin since most of the dietary methionine is obtained from animal proteins. This diet more than halved the cystine output in these patients and was continued without harm for as long as 18 months.

normally secreted during the night constitutes the greatest hindrance to this plan

The regular occurrence of crystalluria in the concentrated morning urines of cystinuric patients was recognized early. Indeed it was believed that the formation of stones takes place only at night [7, 101, 102] and Dent and Senior made this the basis of their treatment regimen [16]. They collected separately the day and night urines of a cystinuric patient and measured the cystine excreted and the urine flow. Averaged results

Fig 42-10 Cystine output per minute at various rates of urine flow in stone-free cystinuric (O) and cystinuric with stones (●). Increased output with higher flow in latter patient indicates dissolution of stone by diuresis. (By permission of C F Dent and B Senior [16])

from their study appear in Table 42.2. There was a constant rate of cystine excretion throughout the 24 hr. During the day the urine flow was adequate to keep the cystine in solution, but at night the decreased urine flow resulted in supersaturation and crystallization even at 37°C. Additional experiments are shown in Fig. 42.11.

Other factors may also be necessary for actual precipitation and accretion of stones. The occurrence of first stones in cystinuric persons at almost any age suggests that all the necessary conditions for stone formation are met infrequently in the day-to-day life of any one individual. It is probable that stones form and grow at night. Perhaps the dilute day urine washes away the nightly deposition. When this undependable equilibrium fails, the cystine stones can grow very rapidly indeed. Not rarely there are recurrences of cystine stones before the patient is dis-

must not be maintained too long however, because of the danger of producing phosphate stones

Alkali therapy was used as early as 1880 by Cantani [98]. He used potassium bicarbonate or citrate in his single patient. Klemperer and Jacoby used the alkali treatment successfully to dissolve a formed stone in 1914 [99]. Others have reported similar successes with sodium citrate or bicarbonate and in some instances have presented radiologic documentation of the dissolution of the stones in as short a period as 1 month. Moderate doses of sodium bicarbonate and water diuresis for 6 weeks enabled one patient to pass 284 stones weighing 10.4 gm in the aggregate [16]. The fact that alkali administration increases the solubility of cystine *in vivo* is further attested by one of the curious misconceptions perpetuated in the medical literature. When cystine excretion was recognized primarily by the presence of crystals in urine, alkali therapy was seen to dissolve the crystals and accordingly was given the credit for stopping the cystinuria. In 1929 [73] and again as late as 1935 [71] it was found necessary to prove that the disappearance of the crystals of cystine during treatment with sodium bicarbonate or citrate does not signify a reduction in cystine output. The limited surface of a stone available for solvent action gives such an unfavorable prospect that the few stones successfully dissolved away are the more remarkable. The prevention of first or recurrent stones would be better achieved by alkali and diuresis than stone removal. As discussed below, alkalinization, like diuresis, must be maintained to be effective and this requires medication during the night.

Dent and Senior were of the opinion that alkali therapy was not necessary if adequate diuresis was maintained [16]. The dissolution of cystine stones *in vivo* by diuresis alone had been reported by Weinberg and Tabenkin [100] as well as by Dent and Senior [16]. In the latter experiments the rates of cystine excretion were compared in two patients, one with renal cystine stones and one stone free (Fig. 42-10). As the rates of urine flow were increased from 1 to 11 ml per min by water diuresis, the amount of cystine excreted per minute by the stone free patient remained constant although the concentration fell considerably. The patient with cystine stones excreted more cystine per minute as the rate of urine flow increased. The concentration of cystine in the latter urine tended to be kept nearly constant by the stone cystine which dissolved.

Diuresis in the past has usually been combined with alkali therapy. The older data available do not permit crediting one or the other with successes achieved but the experiments just cited and the quantitative considerations of cystine excretion and solubility indicate that diuresis is the correct basis of therapy. Any regimen should be so designed that it can be adhered to for years without failure and that it will maintain the desired conditions in the renal collecting tubules and in the bladder throughout the 24 hr. The relatively concentrated and acidic urine

below 500  $\mu\text{g}$  per ml have been maintained in this way throughout the 24-hr period. Under these conditions there are no supersaturated urines and no stone deposition. Any stones already present slowly dissolve.

## SUMMARY

1 Cystinuria is an inherited condition of man characterized by excessive appearance in the urine of cystine, lysine, arginine, and ornithine. No other amino acids are found in excessive amounts. The condition is without deleterious effect on the subject except that cystine tends to precipitate and form stones in the urinary passages with pathologic consequences.

2 Cystine stones comprise approximately 1 per cent of all stones of the urinary passage. Cystine crystalluria is formed in approximately 0.01 per cent of pathologic urine specimens. Chemical cystinuria is found in approximately 1 out of every 250 individuals.

3 The nature of the renal tubular transport of cystine is entirely unknown. The clearance of cystine in normal subjects is approximately 3 ml per min, whereas it may approach the glomerular filtration rate in patients with cystinuria. A favored hypothesis to account for the disease is that a receptor binding substance for the four dibasic amino acids is missing in the homozygous cystinuric person and is present in reduced amounts in the heterozygote.

4 There appear to be two forms of cystinuria. In one the inheritance pattern is recessive and heterozygotes show no noteworthy excess of cystine in the urine. In the other the inheritance is incompletely recessive and heterozygotes show intermediate degrees of cystinuria and may rarely form stones. Possibly the two variants of the disease derive from variant abnormalities of allelic genes.

5 Cystinuria would be an entirely benign disease were it not for the low solubility of cystine, especially in neutral or acid solution. Preventive treatment in the homozygote is directed toward avoiding excess methionine intake, maintaining an alkaline urine by frequent use of alkali and an alkaline ash diet, and more importantly by maintaining at all times a rapid flow of urine. It is particularly important to maintain a large volume of urine during the sleeping hours when normally the urine becomes more concentrated and cystine tends to precipitate. Much can be done with this same regimen to dissolve cystine stones which have already formed.

6 Cystine excretion occurs in the Fanconi syndrome and in Wilson's disease as part of the general aminoaciduria of those diseases. It is seen in species-wide isolated aminoaciduria in the blotched genet, a wild cat of Kenya. It is seen occasionally in several varieties of the dog, but the exact nature of canine cystinuria remains to be ascertained. Recently cystine urinary stones have been encountered in the mink.

Fig 42-11 The nighttime excretion of urine super saturated with cystine pH and cystine concentrations of day and night urines of a cystinuric person over three 24-hr periods (clear columns) are shown. Amount of cystine which could dissolve in true solution in each urine is shown by hatched areas (By permission of C E Dent and B Senior [16])

charged from the hospital following a stone removal. Even high rates of diuresis of over 3 liters per 24 hr produced by daytime water dosage, do not avoid the relatively concentrated urine of the early morning hours.

TABLE 42-2 DAY AND NIGHT VARIATION IN URINARY CYSTINE CONCENTRATION IN CYSTINURIA

| Period         | Rate of excretion of |               | Cystine concentration, µg/ml |
|----------------|----------------------|---------------|------------------------------|
|                | Cystine, µg/min      | Urine, ml/min |                              |
| 6 A.M.-10 P.M. | 538                  | 2.1           | 266 (undersaturated)         |
| 10 P.M.-6 A.M. | 49                   | 0.7           | 103 (super saturated)        |

SOURCE: C E Dent and B Senior [16].

Dent and Senior recommended a regimen of diuresis which avoided the supersaturated urines of early morning. In addition to a high daytime water intake (500 ml every 4 hr) patients were instructed to drink two glasses of water at bedtime and two more at 2 A.M. Periodic tests of the cystine concentration of morning urines were used to check the success of the procedure. Urine flows of 2 ml per min with cystine concentrations

pellagra like rash was most severe. The excretion pattern of amino acids in the urine was identical with that of her brother, E H.

It was clear then that these two siblings were affected by the same disease. An inherited condition seemed probable when it was learned that the parents were first cousins.

### *The Hartnup Family*

Neither parent and none of their six other children gave a clinical history to suggest that they were similarly affected although one girl

### *HARTNUP FAMILY - 1953*

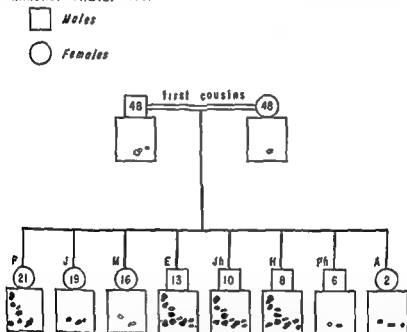

Fig 43.1 The genealogy of Hartnup disease as illustrated in the Hartnup family. The parents were first cousins. The age of the subject in 1953 is indicated by the numbers in the squares and is illustrated the chromatographic patterns of urine samples in two-dimensional chromatograms stained for amino acids.

(M H) was mentally retarded. However two younger siblings of E H, Jh H and H H, also had gross aminoaciduria with the characteristic chromatographic pattern. No abnormality was detected in the urine of the other four siblings or in either parent. In the affected children the amino acid excretion has persisted unchanged in pattern and amount up to the present. The skin and neurologic disturbances have gradually lessened in P H and E H but have made a fleeting appearance in the

## Chapter 43

### Hartnup Disease\*

---

*John B Jepson and Mary Jane Spiro*

Hartnup disease is a familial condition characterized by aminoaciduria and other abnormalities apparently associated with impaired amino acid transport. The publication which first fully reported the existence of this disease [1] bore the title "Hereditary Pellagra like Skin Rash with Temporary Cerebellar Ataxia, Constant Renal Amino Aciduria and Other Bizarre Biochemical Features." As a description of the main aspects of the disease this title cannot be bettered. The family in which the condition was first found consented to the use of their surname *Hartnup*, as an appropriate appellation. The original publication [1] referred only obliquely to the name Hartnup and used the term *H disease*; occasional reference had earlier been made to *Hart's syndrome*.

#### HISTORY

In 1951 a boy aged 12 E Hartnup was admitted to the Middlesex Hospital, London Eng. with mild cerebellar ataxia and a red scaly rash on the exposed areas of his body. His mother avowed that he had pellagra for her eldest daughter (P.H.) with identical symptoms had been treated at the hospital in 1937 for that disease. Although the rash in P.H. was quite consistent with pellagra, other findings were not and a diagnosis of pellagra as a *dietary* deficiency disease was untenable.

Apart from variable cerebellar signs and retarded mental development the only abnormality detected at that time was in the urinary excretion of free amino acids. Paper chromatography of the urine disclosed an excretion pattern of amino acids quite unlike that seen in any other disease.

At about the same time P.H. now aged 19 had a recurrence of ataxia without a rash similar to that which she had had in childhood when the

*younger boys* The mental defect in M H does not seem related to the main abnormality

The pedigree of the Hartnup family (as of 1953), with diagrammatic representation of the chromatographic findings, is given in Fig 43 1 No other relatives of the Hartnup parents show the abnormality

### *Other Cases*

After publication of the definitive report on Hartnup disease in 1956 [1], two cases of 'pellagra' in English children which had been earlier reported [2, 3] were reexamined In the first case, described by Hackish [2], the dietary history was not entirely convincing The second [3 4] was a child with acute psychosis and large quantities of indican in the urine Chromatography of the urines [1] indicated that these two patients were not true dietary pellagrins but had Hartnup disease Seven other cases of Hartnup disease since discovered bring the total to 13 (Table 43 1)

## CLINICAL ASPECTS

The clinical manifestations of Hartnup disease are both intermittent and variable Although the biochemical lesion as represented by amino aciduria is always present clinically recognizable 'attacks' may occur only rarely and in widely different forms

### *Skin Lesions*

In the original Hartnup cases and in most of those found subsequently, the primary cause of referral to hospital has been a red scaly rash, sometimes dry sometimes raw and blistered The rash appears intermittently usually in summertime with a distribution on exposed parts of the face neck hands and legs suggesting photosensitivity [1 6] Hartnup patients learn to avoid exposure to direct light but photosensitivity has not been convincingly demonstrated by experiment The dermatitis closely resembles that seen in dietary pellagra in appearance and distribution

### *Neuropsychiatric Manifestations*

Several of the patients with Hartnup disease have developed a severe but fully reversible cerebellar ataxia These neurologic crises seem to be precipitated at those times when the skin rash is most severe but occasionally they may follow infectious disease without rash [1 6 7] During attacks the patient has an unsteady gait and walks with a wide base Arm movements are jerky and there is an intention tremor Nystagmus and double vision are present No sensory abnormalities are found The ataxia develops suddenly and rapidly reaches a peak The manifestation may vary from day to day Gradual improvement follows over a period of weeks and complete recovery is the rule

younger boys. The mental defect in M H does not seem related to the main abnormality.

The pedigree of the Hartnup family (as of 1953) with diagrammatic representation of the chromatographic findings is given in Fig. 43.1. No other relatives of the Hartnup parents show the abnormality.

### *Other Cases*

After publication of the definitive report on Hartnup disease in 1950 [1] two cases of "pellagra" in English children which had been earlier reported [2, 3] were reexamined. In the first case, described by Hickish [2] the dietary history was not entirely convincing. The second [3, 4] was a child with acute psychosis and large quantities of indican in the urine. Chromatography of the urines [1] indicated that these two patients were not true dietary pellagrins but had Hartnup disease. Seven other cases of Hartnup disease since discovered bring the total to 13 (Table 43.1).

## CLINICAL ASPECTS

The clinical manifestations of Hartnup disease are both intermittent and variable. Although the biochemical lesion as represented by amino aciduria is always present, clinically recognizable 'attacks' may occur only rarely and in widely different forms.

### *Skin Lesions*

In the original Hartnup cases and in most of those found subsequently the primary cause of referral to hospital has been a red, scaly rash, sometimes dry, sometimes raw and blistered. The rash appears intermittently, usually in summertime, with a distribution on exposed parts of the face, neck, hands, and legs, suggesting photosensitivity [1, 6]. Hartnup patients learn to avoid exposure to direct light, but photosensitivity has not been convincingly demonstrated by experiment. The dermatitis closely resembles that seen in dietary pellagra in appearance and distribution.

### *Neuropsychiatric Manifestations*

Several of the patients with Hartnup disease have developed a severe but fully reversible cerebellar ataxia. These neurologic crises seem to be precipitated at those times when the skin rash is most severe, but occasionally they may follow infectious disease without rash [1, 6, 7]. During attacks the patient has an unsteady gait and walks with a wide base. Arm movements are jerky, and there is an intention tremor. Nystagmus and double vision are present. No sensory abnormalities are found. The ataxia develops suddenly and rapidly reaches a peak. The manifestations may vary from day to day. Gradual improvement follows over a period of weeks, and complete recovery is the rule.

microorganisms by utilizing various mutant strains lacking one or another of the enzymes in the sequence of tryptophan synthesizing enzymes. The synthesis of the indole ring of the tryptophan molecule appears to involve the condensation of anthranilic acid with a phosphorylated sugar derivative as shown in Eq (1)

This pathway occurs in *Escherichia coli* [9] *Aerobacter aerogenes* [10] and *Neurospora crassa* [11]. Some strains of *Saccharomyces* appear to utilize a phosphorylated hexose derivative instead of the pentose phosphate [12]. The conversion of indole and L-serine to L-tryptophan by the enzyme tryptophan synthetase, a pyridoxal phosphate requiring enzyme, has been well established [13]. Recently however Yanofsky [11] has proposed the direct utilization of the indoleglyceryl phosphate formed in Reaction (1) without prior splitting to indole and triose phosphate. The reaction as shown in Eq (2) would involve an intermediate step with the indole group attached to the enzyme.

### Degradation

The degradation of tryptophan is of particular interest because of its ultimate conversion to the physiologically important compounds nicotinic acid and serotonin. Figure 43.2 shows the many pathways by which tryptophan may be catabolized.

The overall metabolism of tryptophan in the intact animal has been assessed by the administration of  $C^{14}$  labeled tryptophan to the rat [14, 15]. Because of the rapid conversion of both uniformly labeled and ring labeled tryptophan to  $C^{14}O_2$  and to various Krebs cycle-derived amino acids, it has been proposed that the most important catabolic reaction of tryptophan may be the cleavage of the benzene ring at the level of 3-hydroxyanthranilic acid, with the formation of acetate and other aliphatic intermediates which are finally converted to  $CO_2$ . Further support for this view has been provided. Gholson and Henderson, using an acetate trapping technique [16], found the conversion of the 7  $\alpha$  carbon of tryptophan to the carboxyl carbon of acetate. In addition, Hanks and Henderson [17] found that carboxyl labeled 3-hydroxyanthranilic acid was converted to  $C^{14}O_2$  much more rapidly than could be accounted for by decarboxylation of this compound or its products.

**Formylkynurenine** Tryptophan is first converted to formylkynurenine by the enzyme tryptophan pyrrolase. This reaction has been studied in liver by Knox and Mehler [18, 19] and by Hayaishi and Stamer in

Some patients have never shown severe ataxia, but have experienced a period of "collapsing" or fainting attacks without warning [5] In the case reported by Bickel [8], cerebral involvement was limited to stubborn headache

Psychiatric features have ranged from mild emotional instability to complete delirium, a range similar to that of the psychiatric disturbances of classical pellagra They were the cause for referral to the hospital in only two cases—bizarre delusions and vivid hallucinations in one case [3], and depersonalization in the other (Patient E) [5] The intelligence quotients of the four affected children of the original Hartnup family ranged from 101 in the youngest to 61 in the eldest Baron et al [1] suggested that the biochemical lesion causes progressive mental deterioration, but cases discovered more recently do not lend support to this idea for several of the older patients have average or higher than average intelligence and ability [5, 8] Furthermore the younger Hartnup children have shown no further signs of deterioration, and the older ones have if anything improved

### *Precipitating Factors*

Attacks have been precipitated by fever [1] sulfonamide therapy [6] and psychologic stress [5] In every case there was a history of inadequate or irregular diet (e.g. one patient had lived for months largely on corn flakes [6]) It may be that clinical signs seldom appear unless under the provocation of poor nutrition A variation with age or stress in requirement for some nutrient which is in limited supply because of a biochemical abnormality might explain the clinical deterioration with growth and improvement in adult life This limiting nutrient may be nicotinic acid accordingly a discussion of tryptophan metabolism and the metabolic origins of nicotinic acid is indicated

## METABOLISM OF TRYPTOPHAN

Investigations have revealed a disturbance of tryptophan metabolism manifested by a grossly elevated excretion of urinary indican (indoxyl sulfate) and a high but variable excretion of indolylacetic acid and its conjugates in Hartnup disease In view of the relationships between tryptophan, nicotinic acid and pellagra recent investigations into the primary lesion of the disease have been concerned with the metabolism of indoles It is possible that the appearance of indoles in the urine may prove to be a manifestation of faulty amino acid transport

### *Biosynthesis*

Tryptophan is not synthesized by mammals and is therefore an essential dietary constituent Its biosynthesis has been studied in detail in

*Pseudomonas* [20] Previously the enzyme was called tryptophan peroxidase-oxidase because of its requirement for  $H_2O_2$ . Recently, Tanaka and Knox [21] have demonstrated that  $H_2O_2$  is not directly involved in the reaction but is required only in catalytic amounts for activation of the iron porphyrin portion of the enzyme. In addition Hayaishi et al [22] have found that atmospheric  $O_2$  is incorporated into the formyl kynurenine, and not  $H_2O_2$ . Considerable interest has been shown in tryptophan pyrrolase because of the ease with which increased levels of this enzyme may be induced by tryptophan administration as was originally demonstrated by Knox and Mehler [23].

**Kynurenine** The formylkynurenine produced by tryptophan pyrrolase is hydrolyzed to formic acid and kynurenine by the enzyme formylase which is also present in liver [18-19]. Kynurenine may then take part in the three pathways shown in Fig 43-2. The conversion of kynurenine to 3-hydroxykynurenine occurs in kidney and liver mitochondria in the presence of TPNH and  $O_2$  [24]. Atmospheric  $O_2$  is incorporated into the hydroxyl group in this reaction [25]. Both kynurenine and hydroxykynurenine are cleaved by the enzyme kynureninase to alanine plus anthranilic or 3-hydroxyanthranilic acid respectively. Because of the pyridoxal phosphate requirement of this enzyme [26] the metabolism of both kynurenine and hydroxykynurenine is altered in pyridoxine deficiency and appears to be shunted through the kynurenine transaminase reaction with the formation of the corresponding  $\alpha$  keto acids. These cyclize spontaneously to kynurenic and xanthurenic acids as is evidenced by the finding in the urine of pyridoxine deficient animals of large amounts of kynurenine, kynurenic acid and xanthurenic acid as well as other tryptophan derivatives in which the side chain is still intact [27].

Anthranilic acid is apparently not formed under normal circumstances and administered anthranilic acid is excreted unchanged or as various conjugates [28]. Hydroxyanthranilic acid on the other hand is already stated [17] is very active metabolically. When  $C^{14}$  labeled 3-hydroxyanthranilic acid is injected into rats the activity appears rapidly as  $CO_2$  and much smaller amounts of quinolinic acid, N-methylnicotinamide and picolinic acid. The steps by which these conversions are thought to take place involve the cleavage of the benzene ring between carbons 3 and -4 with the formation of an aldehyde intermediate which has been isolated by Wiss et al [29-30]. It is thought that enzymatic ring closure and decarboxylation occur simultaneously with the formation of either nicotinic acid or picolinic acid each by its specific enzyme. Uncertainty remains as to whether quinolinic acid is an intermediate in these reactions. Hanks and Segel who injected tritium labeled quinolinic acid into rats demonstrated the conversion of this compound to urinary N-methylnicotinamide [31]. However Mehler [32] is studying the enzyme picolinic carboxylase which converts the oxidized intermediate of hydroxy

Fig. 43-2 Metabolic pathways which are open to tryptophan. Main pathways are shown in bold arrows.

## METABOLIC ABNORMALITIES

## AMINO ACIDS

*Aminoaciduria*

The pattern of the aminoaciduria in Hartnup disease is more significant than the total amount of amino acids excreted so that chromatography must be used in the diagnosis. The amounts of amino acid excreted vary from case to case and may be slightly affected by diet but are usually increased at least tenfold over the normal. This absolute amount of amino acids excreted is comparable to that sometimes reached in other types of aminoaciduria such as lanconi syndrome (see Chap 37) Table 43 2

shows some reported values. The amino acid index (percentage of total urinary nitrogen contributed by  $\alpha$  amino acid nitrogen) is five to seven times as high as normal.

The amino acid pattern as disclosed by paper and ion-exchange chromatography is quite unlike that in any other type of generalized aminoaciduria (Fig 43 3). The striking similarity of the findings in urine specimens from different patients is apparent in Fig 43 1. The amino acid pattern found in Hartnup disease is compared with that from a normal individual in Fig 43 3. Fig 43-4 shows how it appears in two different solvent systems.

The free amino acids which are excreted in amounts five to ten times normal are alanine, serine, threonine, asparagine, glutamine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, histidine, and citrulline. Substances which can be detected by chromatography but which are present in normal or only moderately increased amounts are taurine, glycine, cystine, aspartic acid, glutamic acid, lysine, methylhistidine, and  $\beta$  amino isobutyric acid. Even the most sensitive reagents

anthranilic acid to picolinic acid, found that quinolinic acid is not decarboxylated

**Nicotinic Acid** The enzyme system converting the oxidized intermediate of 3-hydroxyanthranilic acid to nicotinic acid has not yet been studied in detail. Mehler et al [33] have shown that the relative amounts of picolinic acid and nicotinic acid formed from hydroxyanthranilic acid depend on the relative activity of these two enzymes. In the alloxan diabetic rat the activity of the enzyme picolinic carboxylase is considerably increased. This favors a production of picolinic acid rather than nicotinic acid and accounts nicely at an enzymatic level for the decreased excretion of N-methylnicotinamide in this animal.

From a quantitative point of view very little tryptophan appears to be converted to nicotinic acid in the normal state. The dietary equivalent of 1 mg niacin is approximately 60 mg tryptophan [34].

**Serotonin** Under normal conditions the conversion of tryptophan to 5-hydroxytryptamine (serotonin) and 5-hydroxyindoleacetic acid are minor pathways. In patients with malignant carcinoid however large amounts of 5-hydroxytryptamine and 5-hydroxyindoleacetic acid are excreted in the urine [35] and the blood level of serotonin is much increased over the normal [36]. It seems clear that serotonin is produced by the decarboxylation of 5-hydroxytryptophan rather than by hydroxylation of tryptamine [37-38]. The site of formation of 5-hydroxytryptophan is not known although the argentaffine cells have been proposed as a likely site [39]. The enzyme 5-hydroxytryptophan decarboxylase is widely distributed and requires pyridoxal phosphate [40]. Weissbach et al have demonstrated that 5-hydroxytryptamine is converted to 5-hydroxyindoleacetic acid by way of the intermediate 5-hydroxyindoleacetaldehyde [41].

**Indoles** Another pathway of tryptophan metabolism is conversion to indolic acids. Armstrong et al have shown that normal urine contains a large number of indolic acids the main ones of which are indoleacetic acid, indolelactic acid, 5-hydroxyindoleacetic acid and indoleacetyl glutamine [42]. Studies by Weissbach et al [43] have indicated that the indoleacetic acid excreted is a product of the metabolism of both intestinal microorganisms and mammalian tissues. This conversion occurs mainly by transamination of tryptophan to indolepyruvic acid with subsequent decarboxylation to indoleacetic acid. Small amounts of tryptophan are also converted to indoleacetic acid by way of tryptamine.

Another important product of the metabolism of tryptophan by the intestinal microorganisms is indole which is formed from the splitting of tryptophan to indole and pyruvic acid by the enzyme tryptophanase [44]. Indole absorbed from the intestine is hydroxylated in the 3 position to form indoxyl and is then conjugated primarily with sulfate. This detoxication occurs mainly in the liver [45].

These excretion studies indicate a highly specific disturbance of the renal tubular reabsorption of certain amino acids. No other renal abnormalities have been detected. Other clearance measurements and tests of tubular function have given perfectly normal results [1]. No reducing sugars are found. The mother of the Hartnup family showed no

Fig 43-4 Chromatogram of a urine sample from a patient with Hartnup disease in two different solvent systems. On the left the second chromatographic system was butanol-acetic acid-water and on the right the second chromatographic system was a butanol-pyridine-water system. In each case the first chromatographic solvent system was phenol ammonium. The urine was dealted.

evidence of an abnormal amino acid clearance even in response to an oral casein load.

Although the defect in renal reabsorption is easy to demonstrate, this does not mean that it is necessarily the primary or only cause of the functional disturbances. In current opinion, based on the work of Milne [49]

TABLE 43-3 RENAL CLEARANCE OF AMINO ACIDS IN HARTNUP DISEASE

| Amino acid                   | Excretion in Hartnup disease | Clearance ml per min |        |
|------------------------------|------------------------------|----------------------|--------|
|                              |                              | Hartnup              | Normal |
| Total amino acid N           |                              |                      |        |
| Fasting                      | High                         | 6-22                 | 1.5    |
| Maximum on oral protein load | Very high                    | 25-50                | 3.0    |
| Threonine                    | High                         | 70                   | 1.0    |
| Tyrosine                     | High                         | 66                   | 1.5    |
| Histidine                    | High                         | 122                  | 6.0    |
| Taurine                      | Low                          | 1.9                  | 5.0    |
| Proline                      | Low                          | 0.3                  | 0.1    |
| Cystine                      | Low                          | 0.4                  | 0.5    |
| Lysine                       | Low                          | 3.0                  | 0.4    |

have failed to detect significant amounts of proline, hydroxyproline, methionine or arginine. The failure of Evered [46] to detect tryptophan in Hartnup urine is probably due to the destruction of this amino acid on cation exchange resins.

Perhaps the most striking differences between the Hartnup pattern and those of other generalized aminoacidurias such as Fanconi syndrome (Chap 37), Wilson's disease (Chap 25) and galactosemia (Chap 7) is

the absence of an abnormality in proline excretion. The quartet of amino acids found in cystinuria (viz, cystine, lysine, arginine, and ornithine, cf Chap 42) is excreted normally in Hartnup disease. The free amino acids are all of the L-configuration [47].

The excretion of free glutamic acid and aspartic acid is low (as in normal urine) but that of the respective amides is very high. If the urine is left at room temperature for a few hours the level of free glutamic acid rises at the expense of glutamine but specimens can be kept deep frozen for years without deterioration.

Acid hydrolysis of the urine releases no new amino acids and relatively little additional amino acid nitrogen although increased excretion of certain conjugates (e.g. hippuric acid and indolylacetylglutamine) undoubtedly occurs.

The aminoaciduria is of renal origin and not an overflow phenomenon. The renal clearance of total amino acid nitrogen both in the fasting state and following an oral load of casein is very much higher than normal [48]. Similarly the renal clearances of those individual amino acids which are excreted in excess are grossly elevated above normal although the clearances of the amino acids which are not excreted in excess are but little elevated [46]. Table 43.3 gives some examples from the work of Dent [48] and Evered [46]. The high clearance of 122 ml per min for free histidine, a figure now exceeded by the 140 ml per min in a case reported by Jonus [7] approximates the normal glomerular filtration rate and suggests a complete lack of reabsorption.

Fig 43.3 The excretion of free amino acids in the urine of normal subjects and patients with Hartnup disease.

detectable, even when L-tryptophan was fed in addition [1]. A similar result was obtained using neomycin [54] but succinyl sulfathiazole for 7 days had no effect [4, 56]. These antibiotics did not alter the urinary amino acid excretion and the indicanuria returned to its high level a few days after the cessation of treatment.

The indican could be raised considerably by oral administration of protein or L-tryptophan [1]. Milne [49] has followed this process with chromatograms of serial samples of urine. In normal subjects there was a variable rise in indican followed by a logarithmic fall but in Hartnup

Fig 43-5 The indoxyl compounds found in the urine of patients with Hartnup disease

disease there was a greatly raised excretion which reached a maximum after 12 hr and persisted for more than 24 hr.

The urinary indoxyl derivatives presumably are final excretory products formed in the liver from indole absorbed from the gut where it arises from the action of intestinal microorganisms on unabsorbed tryptophan. The magnitude of this process in Hartnup disease could be due either to an increased growth in the gut of a particular flora or to delayed absorption of tryptophan or to both. For one might determine the other. There is little or no excretion of 5-hydroxytryptophan sulfate, the product of tryptophan formation characteristic of the malabsorption syndrome [57, 58]. Hence the responsible microorganisms may be different in Hartnup disease.

Rodnight and Mellman [4] suggested that the "pellagra" of their case was caused by the diversion of tryptophan from its normal metabolic course into the wasteful pathway of indican formation. Thus it is not the only drain of tryptophan; however, there is not only the variable loss as indican (representing 20 per cent of the daily tryptophan intake) but also the loss as free amino acid and derived indolic acids as well.

(see below) it is only one manifestation of a wider derangement of amino acid transport in this disease.

### Plasma amino acids

The amino acid concentrations, as determined by ion exchange chromatography [46] are about 30 per cent lower than normal. In the case of tryptophan, this has been confirmed by spectrophotofluorometry [50]. The following values were found for free tryptophan in plasma from three of the Hartnup boys.

| Subject | Age yr | Iminoaciduria | Plasma tryptophan $\mu\text{g/ml}$ |
|---------|--------|---------------|------------------------------------|
| Jh H    | 14     | +             | 6.2                                |
| H H     | 12     | +             | 7.8                                |
| Lh H    | 11     | -             | 10.6                               |

Westall [52] has reported that the plasma tryptophan level in normal children below 3 years of age is low, but above this age a very constant figure of  $11 \pm 1 \mu\text{g per ml}$  is found.

### METABOLITES OF TRYPTOPHAN AND INDOLE

Early in the investigations of the Hartnup family [1], a high but variable urinary excretion of indigogenic material (indican) was apparent. This led to a more complete investigation of urinary indoles by paper chromatography. A raised excretion of the indolic acids derived from tryptophan was thus revealed but this has not proved to be so constant a feature of the disease as was first thought.

### Indicanuria

All individuals with 'Hartnup' aminoaciduria also excrete large amounts of indicans. The reverse is not true. For example patients with 'blind loop syndrome' excrete much greater quantities of indicans but do not develop aminoaciduria [51]. The urinary indican from individuals with Hartnup disease is almost entirely indoxyl sulfate (I<sub>16</sub>, 41.5), but a small amount of indoxyl  $\beta$  glucuronide (I<sub>16</sub>, 43.5) can accompany it [1, 51]. Another indoxyl derivative (although not indigogenic) found in Hartnup urine is bis-indolyl indoxyl (I<sub>16</sub>, 43.5) which is invariably produced during enzymic oxidation of indole [53, 54].

The only accurate measurements of the indican excretion in Hartnup disease are those of Rodnight [1, 5]. His cases excreted 200 to 400 mg per day compared with 100 or less in normal subjects of the same age. Semiquantitative measurements based on chromatographic comparisons showed that indican excretion fell rapidly during a course of chlor tetracycline. After only 4 days on the antibiotic indican was no longer

Fig 43-7 Urinary indole patterns in Hartnup disease. *Left* Paper chromatogram of urine from patient E H [2] 100  $\mu$ l urine were chromatographed with ascending solvents isopropanol ammonia first and up butanol acetic acid second right to left. Compounds were located with p-dimethylamino benzaldehyde (Ehrlich reagent). The key is found in the right hand photograph. Note the central urea spot (normally yellow) the indican spot (IS) (brown) and the triad of spots due to indolylacetic acid (IAA) indolylacetyl glutamine and tryptophan. This pattern is typical of Hartnup disease although the relative intensity of spots is variable. *Right* Paper chromatogram of urine from patient G [3] This chromatogram shows an additional spot due to indolylactic acid (ILA) not found in other cases of Hartnup disease (By permission of D N Baron et al [1] and J H Jonxis [7])

total IAA were 27 and 15 mg respectively = normal sister excreted 93 mg. The Hartnup boy (E H) who had the very high IAA excretion during 1951-1954 had a normal IAA excretion when measured in 1959 when he was 20 years old. In 1957 colorimetric determinations of free and combined IAA [49] in urines from the other Hartnup boys gave the following results [51]

| Subject | Age y | Aminoacids in | Free IAA | Conjugated IAA |
|---------|-------|---------------|----------|----------------|
| J H     | 14    | +             | 15       | ■              |
| H H     | 12    | +             | 45       | 25             |
| Ph H    | 11    | -             | 2        | ■              |

It appears that the raised IAA excretion which has been found in all cases of Hartnup disease tested before the age of 12 gradually disappears as the patient grows older although the high amino acid excretion remains.

#### Effect of Tryptophan Loading

If patients with Hartnup disease are given an oral load of tryptophan a grossly abnormal excretion of indolic acids follows [1] even if there was

### Indolylacetic Acid and Its Congeners

Paper chromatographic studies revealed that EH the first of the Hartnup family investigated, excreted indolylacetic acid (IAA) (Fig 43 6A) at a considerably higher level than normal [1] This was particularly true during his acute bouts of ataxia and rash, but even after clinical recovery the urinary abnormality was present The IAA was always accompanied by a conjugation product, originally called U1 [59] but later identified as indolylacetyl L-glutamine (IAc GluNH<sub>2</sub>) (Fig 43 6B) [60] This conjugation product is the one expected from the liver "detoxication" of IAA in man The other possible conjugate

Fig 13-6. Derivatives of indole found in normal subjects and patients with Hartnup disease. See text.

indolylacetyl glucuronide (Fig. 4) [6C], has been present occasionally but only in moderate amount [8].

These indoles after two dimensional paper chromatography and location with Ehrlich reagent [69 62] showed a distribution pattern quite as characteristic as the amino acid pattern (Fig 43 7) Similar indolic patterns were found with urine from the other affected members of the Hartnup family the unaffected members had normal (barely detectable) excretion of indolic acid During one period of hospitalization the free IAA excretion in E H varied from 50 to 200 mg per day on a normal varied diet A normal excretion would be less than 10 mg per day

The constancy of the findings reported above strengthened by the discovery of similar (but variable) indolic acid excretions in some other cases [16] has been challenged by three later findings

1 In one case of Hartnup disease [8] the urinary IAA (68 mg per day) was accompanied by indolylactic acid (ILA) (Fig 43 6D) in an amount approaching that found in phenylketonuric patients (Chap 10) although no ortho- or *p*-hydroxyphenyllactic acid accompanied it [63] (Fig 43 7). ILA has not been detected in any other case of Hartnup disease.

2 The excretion of IAA as of other weak acids is influenced by the urinary pH being promoted by mild alkalosis and reduced by acidosis [49]. Measurements are not strictly comparable unless made under similar acid base conditions.

3 Two female siblings aged 23 and 24 investigated by Hersov and Rodnight [5] had no elevated excretion of IAA. Their daily excretions of

The whole blood and serum levels for serotonin (5-hydroxytryptamine) were on the low side of the normal range in parallel with the low urinary 5-HT and 5-HIA excretions [51]. This may represent a slight diversion of tryptophan from serotonin formation.

#### *Nicotinic Acid Intermediates*

Because of the pellagra like symptoms of Hartnup disease a possible enzymic block in the usual tryptophan kynurenine nicotinic acid pathway (Fig 43-2) was early suspected [1]. In one patient on a normal diet the urinary excretion of nicotinic acid and its derivatives was on the low side of normal and was surprisingly little elevated by oral administration of tryptophan [1]. The same was true of the excretion of kynurenine as seen chromatographically [51] and of kynurenic acid and xanthurenic acid in other cases [5].

Milne [49] has now compared the rise in urinary kynurenine which follows tryptophan ingestion in normal persons and in patients with Hartnup disease. Normal persons excreted 5 to 10 per cent of oral L-tryptophan as kynurenine but in Hartnup disease the conversion was only 0.5 to 1.5 per cent.

#### *Other Biochemical Investigations*

Considering the magnitude of the Hartnup amino acid lesion it is remarkable how normal the other biochemical and physiologic processes appear to remain. Two studies bear on the part played by microorganisms in the metabolic defects. In normal subjects the gut organisms are probably responsible for the production of many of the phenolic acids excreted. The urinary pattern of phenolic acids in Hartnup patients receiving a normal diet is normal [13]. Investigations of the fecal porphyrins in E. Hartnup [162] disclosed that these were generally high but that they varied in a surprising way. For example on one occasion 3 days of oral chlortetracycline lowered the protoporphyrin content of the feces from 74 to 11  $\mu\text{g}$  per gm while the same antibiotic given 1 year later raised the fecal protoporphyrin more than tenfold.

### METABOLIC LESION OF HARTNUP DISEASE

One might hope that all the clinical and biochemical features of Hartnup disease could be unified under a single metabolic block. The following biochemical findings would have to be rationalized:

- 1 The specific aminoaciduria
- 2 The retarded absorption of tryptophan from the gut
- 3 The raised production of IAA which probably diminishes with the age of the subject

normal excretion of IAA before the load [49] In normal subjects 70 mg per kg L-tryptophan causes a sharp rise in IAA and a smaller rise in ILA The peak is reached after 2 hr and the level falls to normal values in 12 hr In Hartnup disease the rise is somewhat higher and persists at a high level for at least 24 hr Residual free tryptophan may appear in the feces If DL-tryptophan is fed to normal subjects, ILA appears in the urine in large quantities It is presumably formed from absorbed L-tryptophan by the action of an amino acid oxidase

Hartnup patients react quite differently There is little excretion of ILA Most of the L-tryptophan is recovered from the feces Milne's conclusion from these experiments [49] is that there is a defective absorption of L- and of D-tryptophan from the jejunum The absorption block for D-tryptophan is thought to be virtually complete, the partial block for L-tryptophan would prolong its oxidative metabolism to IAA, but whether this occurs in the tissues or in the gut must await the results of studies after administration of antibiotics The excretion of IAA by normal subjects is only partially suppressed by neomycin or tetracycline [48] and in one Hartnup patient was actually raised by chlortetracycline [1] presumably because tryptophan was no longer diverted to indican

#### *Other Urinary Indoles*

Another indolic acid which has been found in urine of patients with Hartnup disease is indolylacryloyl glycine (Fig 43 6E) This is the expected conjugation product of indolyl acrylic acid This compound which reacts atypically with Ehrlich reagent, was first described by Kimmig [64] in urine from patients with light sensitive dermatitis It is excreted by man after the ingestion of indolylpropionic acid Urine from a Hartnup patient on a normal diet contains much more indolylacryloyl glycine than does normal urine [51] and its excretion is stimulated after an 8 hr lag period by oral administration of tryptophan [49] Chromatographic methods have failed to show indolylpyruvic acid or its decomposition products in urine [65 61, 6a]

The urinary excretion of tryptamine in Hartnup patients is normal [5] This may only be tryptamine produced locally in the kidney tubules and gives no indication of tryptamine formation in other tissues

#### *Indolic Acids in the Blood*

The whole blood and plasma indolic acids have been studied chromatographically in some cases of Hartnup disease [6 51] Apart from a slightly elevated concentration of indoxyl sulfate patients and normal subjects were indistinguishable The renal clearance values for indolic acids are normally very high [66] and there is no evidence that they are raised higher in the disease The clearance of IAA  $\text{GluNH}_2$  is at least 150 ml per min and may be synthesized at least in part from IAA in the kidney

lead to an increased metabolism along alternative pathways to indolyl pyruvic acid or tryptamine and thence to IAA. It is noteworthy that the quite different shunt of tryptophan metabolism in carcinoidosis also leads to pellagra like rashes ✓

The other biochemical abnormalities would be considered consequences of endogenous nicotinic acid deficiency at the cellular level. For example the aminoaciduria would be a result of cessation of tubular reabsorption consequent to the nicotinic acid deficiency.

It is unlikely that IAA has toxic consequences. Consumption in vast quantities as an insulinase inhibitor [72] does not cause aminoaciduria to develop [61] but IAA does have important effects on membrane permeability and amino acid uptake in plant cells.

### *Abnormal Intestinal Bacteria*

It seems improbable that the primary abnormality of Hartnup disease lies in an unusual type or concentration of microorganisms. It is much more likely that a tissue dysfunction promotes the growth of an unusual flora. Thus retention or secretion into the gut of amino acids or indoles could provide an environment favorable for abnormal flora. It is known that the oral administration of methionine causes distinct changes in the urinary indole chromatograms from Hartnup patients [60].

### *Amino Acid Transport*

The most acceptable hypothesis for the primary lesion in Hartnup disease is that the transport of amino acids into cells is defective [49]. The defect would have to involve at least the cells of the proximal renal tubules and of the jejunum in order to account for the aminoaciduria and the retention of tryptophan in the lumen of the gut. It is not yet known whether those amino acids which are poorly reabsorbed by the renal tubule are also poorly absorbed from the gut nor why some amino acids do not appear in Hartnup urine at all.

It has recently been suggested by Dickinson [73] that xanthinuria<sup>1</sup> (Chap 22) is an example of a renal defect of purine reabsorption chemically coupled with a specific xanthine oxidase deficiency, a possibility already predicted by Harris [74]. Hartnup disease may be another example i.e. the specific defect of tryptophan pyrrolase (oxidase) deficiency associated through some unknown common factor with a less specific deficiency of amino acid transport in renal and intestinal cells.

Whatever the ultimate cause of Hartnup disease may prove to be the abnormal metabolism of tryptophan may only reflect the experimental ease with which its degradation products can be measured. There is of course considerable diversion of tryptophan from its normal metabolic

4 The low experimental conversion of oral tryptophan along the nicotinic acid pathway

5 The harboring of gut microorganisms with a special aptitude for the conversion of tryptophan to indican

Three possibilities for the primary lesion are immediately obvious and were discussed in the definitive paper [1]

1 A block along the metabolic sequence from tryptophan through kynurenine to nicotinic acid

2 An intestinal habitat which supports a bacterial flora so abnormal that the metabolism of the host is affected

3 A disorder of amino acid transport in the cells of the kidney tubules and in the gut

### *Tryptophan Metabolism and Nicotinic Acid*

A considerable fraction of dietary tryptophan is normally available for the synthesis of nicotinic acid. It is possible that some tissue systems obtain their required nicotinic acid preferentially (or only) from the *in situ* metabolism of tryptophan rather than from dietary nicotinic acid. Since the conversion of dietary tryptophan to kynurenine and nicotinic acid derivatives is greatly impaired in Hartnup disease it is possible that an 'endogenous' nicotinic acid deficiency could develop. One might then account for the signs of pellagra especially under conditions of growth or stress. Nicotinamide deficiency leads to mental deterioration [68].

A genetically determined metabolic block most probably would involve tryptophan pyrrolase, an enzyme which normally catalyzes the oxidation of tryptophan to formylkynurenine [21]. This is an adaptive enzyme which is absent in fetal tissue but develops dramatically after birth. If this is the deficient enzyme in Hartnup disease the condition is a carry over of the fetal condition into postnatal life [69]. The clinical improvement in adult life might represent a gradual adaptive appearance of tryptophan pyrrolase. If the 'substrate adaptation' feature of the enzyme really is a stabilization by tryptophan [70] then the Hartnup enzyme would have an abnormal lability. On the other hand there is yet no proof of an actual deficiency of enzyme and the apparent deficiency might equally well be a reflection of reduced availability of tryptophan.

Snyder [71] has considered that Hartnup disease is due to dysfunction of an apoenzyme requiring nicotinamide as a cofactor but there is little evidence in support of this view.

The shunting of tryptophan from nicotinic acid formation would

Hartnup disease should be suspected in patients with the following signs pellagra not due to gross dietary deficiency photosensitive rash especially if accompanied by neurologic changes reversible ataxia especially when siblings are affected similarly a high excretion of indican or indolylacetic acid

## GENETICS

The 13 known cases (4 males 9 females) are distributed among 8 families with a total of 32 children (Table 43 1). Siblings are affected in 3 families 4 out of 8 in one family [1] 2 out of 3 in another [5] and 2 out of 9 in the third [7]. In 2 of these families the parents are first or second cousins 1 or 4 other families [5 6 8] no blood relationship between parents could be established even back to 1416 in the last case. Five of the families come from England 2 from Holland and 1 from Germany but no ethnic pattern is discernible. No cases have been reported in the United States.

Obviously these figures are insufficient to warrant conclusions about either mode of transmission or prevalence of the disease. If the disease is genetically determined it swells the list of those hereditary abnormalities which are not apparent at an early age but appear only under the stimulus of some external or internal metabolic influence. Although the disease appears to be rare it may be that the rarity resides in the appropriate or adequate stress rather than in the genetic existence of susceptibility.

A possibility remains that an abnormal gut flora is solely responsible for the manifestations of Hartnup disease. If this should prove to be true the condition could still be called hereditary provided that the abnormal flora were encouraged by a genetically determined vagary of the host [1].

If Hartnup disease is transmitted as an autosomal recessive trait as the original pedigree suggests affected individuals would be homozygous for the condition and both their parents would be heterozygous carriers. It might be expected that heterozygotes would show a less marked expression of the condition at the site of the primary metabolic defect. Perhaps this could be used to show which of several alternative metabolic lesions is the most likely [60].

Most of the parents and near relatives of Hartnup patients have been tested for aminoaciduria and all are uniformly negative [6]. The mother of the Hartnup children had a normal amino acid clearance even in response to a casein load [48] but a single experiment [51] suggested that she responded to an oral load of L-tryptophan with a higher than normal excretion of indolylacetic acid and a lower than normal conversion to nicotinic acid intermediates. Two of the affected girls are married but

routes and it is reasonable to suggest that the clinical aspects of Hartnup disease may result from one or more of the following

- 1 Lowered production of endogenous nicotinic acid
- 2 Increased absorption of indole from the gut
- 3 Tissue or gut formation of tryptamine [70]
- 4 Chronically low level of plasma tryptophan

## DIAGNOSIS

The only constant feature of Hartnup disease is the characteristic excretion of free amino acids and it is upon this that diagnosis must be based. The *pattern* of excreted amino acids, rather than the total amino acid excretion is the determining factor. It is not sufficient to measure total amino acid nitrogen even though a low total value would exclude the disease.

Any of the simple two dimensional paper chromatographic systems and location agents for amino acids [76] will serve. Figures 43-3 and 43-4 show the urinary amino acids expected in Hartnup disease [108]. A volume of urine corresponding to a 2 sec excretion from a 24 hr collection on a normal or low protein diet will give intensely reacting spots with the ninhydrin reagent. Normal urine shows very little. Desalting is hardly necessary with this small volume. The Hartnup amino acid pattern has never changed in any of the patients during the years they have been studied. Patients show only the most minor variation in pattern and nothing like it has been found in any other condition.

The only alternative diagnosis for Hartnup disease would be pellagra, and in the few cases of true dietary pellagra examined [1, 51] the amino acid excretion was low or normal.

The indolic excretion is not constant enough to be the basis of a diagnostic test but the abnormal response to oral L-tryptophan loading accompanied by paper chromatography of serial samples might be used [49]. Hartnup disease would be associated with a greater than normal excretion of indolylacetic acid and of indican persisting for 24 hr at least. A semiquantitative test tube method is suggestive e.g. the Obermeyer test for indican or the Weissbach test [77] for indolic acids.

Mix 1 ml urine, 2 drops concentrated HCl and 1 ml CHCl<sub>3</sub> shake well, centrifuge and reject aqueous layer, mix with 1 ml 0.5 per cent Ehrlich reagent in 12 N HCl wait 10 min, mix with 0.5 ml ethanol, add 1 drop 2.5 per cent NaNO<sub>2</sub>. An immediate blue color indicates urinary indolic acids at a level above 50 µg per ml.

Hartnup disease is not excluded by a normal indole excretion but all patients with a high indican or high IAA excretion [43] should be further examined for the Hartnup amino acid excretion pattern.

c A disorder of amino acid transport into cells particularly those of the renal tubules and the jejunum accounts for the constant aminoaciduria and for the slowed absorption of tryptophan. The latter permits an abnormally large formation in the gut of indican and may also sponsor the appearance of an unusual intestinal flora. The clinical manifestations arise through the consequent deviation of dietary tryptophan from its normal metabolic routes especially that leading to nicotinic acid.

The evidence favors the third interpretation of the abnormality of Hartnup's disease.

6 Insufficient number of patients with this disease has come to attention to permit certainty regarding its inheritance pattern but information at present is consistent with autosomal recessive transmission.

7 Patients have responded satisfactorily to oral administration of nicotinamide. A diet high in protein may be of value as well.

neither has children. Further elucidation must await the discovery of many more cases and of a test for genetic carriers of the condition.

## TREATMENT

The paucity of cases and their variability has not made it easy to evaluate possible courses of treatment. Similarity of the symptoms to pellagra has led in many instances to oral nicotinamide therapy (40 to 200 mg amide or acid per day). Marked improvement in the dermatitis and neurologic picture has usually followed, but such improvement may occur without treatment. In view of the high urinary loss of amino acids, a high protein diet or supplement has been prescribed and seems beneficial.

## SUMMARY

1 Hartnup disease is characterized by an intermittent red scaly, pellagra like rash appearing after exposure to sunlight, attacks of cerebellar ataxia and occasionally by psychiatric changes ranging from emotional instability to delirium. Progressive mental deterioration was suggested from the original study of the Hartnup family but this has not been supported by patients subsequently encountered.

2 The disease was originally observed in 4 out of 8 offspring of a first cousin marriage. Further patients, including 3 more sets of siblings have brought the total of known cases to 13.

3 The single recognized constant feature of the disease is a massive aminoaciduria renal in origin and characteristic in pattern. This provides the only certain diagnostic test.

4 All patients excrete large but variable amounts of indoxyl sulfate (indican) in the urine. This disappears if the gut is sterilized with antibiotics. Also in most cases there are abnormally large amounts of indolyl acetic acid and its conjugates. Following oral administration of a loading amount of L-tryptophan there is a high and prolonged conversion to urinary indolylacetic acid coupled with a lower than normal conversion to kynurenine and nicotinamide.

5 Three possibilities have been considered for the primary genetically determined biochemical lesion.

a An enzymic block along the metabolic sequence from tryptophan through kynurenine to nicotinic acid with necessary diversion of tryptophan degradation. The aminoaciduria, the abnormal gut flora and the clinical symptoms develop because of a deficiency in the intrinsic production of nicotinic acid.

b An abnormal intestinal environment supports a gut flora which deranges the metabolism of the host.

## Chapter 44

### Hypophosphatasia

---

*Frederic C. Bartter*

#### DEFINITION AND GENERAL DESCRIPTION

Hypophosphatasia is a familial disease characterized by abnormalities of the skeleton decreased serum alkaline phosphatase and the appearance of phosphoethanolamine in the plasma and urine. Hypercalcemia renal damage and occasionally premature synostosis of the cranial vault may also be found.

#### HISTORICAL ASPECTS

Although the disease was first given its present name by Rathbun [1] in 1948 there are scattered reports of what is undoubtedly the same entity going back 20 years before that time. The historical aspects are covered in detail in the reviews by Fraser [2] and by Currarino and associates [3]. The following reports are of especial interest in the development of currently accepted concepts of the disease. Huhne [4] in 1929 described a patient with a syndrome clearly recognizable in retrospect as hypophosphatasia. Chown [5] in 1935 described two further patients with nephrocalcinosis at autopsy. Kubatsch [6] in 1938 described a patient with islands of bone in the skull whose father had evidence of premature synostosis. Alkaline phosphatase values were not reported in any of these cases. Anspach [7] in 1939 noted hypercalcemia in a child with pathognomonic changes in the bones including premature synostosis. Serum alkaline phosphatase concentration in this child determined on a number of occasions was very low with a single exception in early infancy. Macey [8] in 1940 described two brothers (one 36 years of age) with hypophosphatasia who gave a history of severe rickets in childhood and of numerous fractures in adult life. Rathbun in his classical description of the syndrome reported that alkaline phosphatase activity was low in bone intestinal mucosa and kidney. Sobel

and increase in intracranial pressure may occur convulsions serious brain damage and death may ensue if surgical decompression is not performed The late manifestations are those of oxycephaly The sutures may show the characteristic prominent bony ridges Subperiosteal new bone formation not normally seen in rickets has been reported in three cases [1, 2 17] Premature loss of teeth is occasionally seen

A

B

Fig 44-1 X ray of the shoulder (A) and wrist (B) of a 39 month-old female with hypophosphatasia Note defects in epiphyseal ossification (By permission of Dr Edna Sobel)

Hypercalcemia is common especially in infants and hypercalciuria results The nausea and vomiting of some patients may be in part attributable to the hypercalcemia

Four cases have been observed first as adults [8 18 19] In two brothers rickets was said to have been present up to the age of 4 followed by an interim period of apparently normal health for a number of years The patients finally came to medical attention with pseudofractures one showing evidence suggestive of craniostenosis in childhood In the third adult patient rickets had been suspected in childhood The fourth had osteoporosis hypophosphatasia and phosphoethanolaminuria found

and associates [9] in 1953 considerably advanced the knowledge of this syndrome. In their patient they noted for the first time premature loss of teeth as part of the syndrome and observed that the serum did not inhibit normal phosphatase activity. They found low alkaline phosphatase activity in bone, cartilage, liver and a tooth, and finally presented data strongly suggestive of hypersensitivity to vitamin D in their patient.

Fraser and associates [10] and McCance and associates [11] discovered simultaneously in 1954, that the excretion of phosphoethanolamine in the urine is an integral feature of the disease. They showed also that the parents of patients might have abnormally low serum alkaline phosphatase values. Fraser et al [10] found that phosphoethanolamine might appear in the plasma of patients and in the urine of the otherwise normal parents of patients with hypophosphatasia. Fraser [12] also showed that the cartilage of rachitic rats would calcify in the serum of patients with hypophosphatasia but that costochondral cartilage and osteoid from a patient would not calcify in the serum of normal people or in a synthetic medium containing appropriate concentrations of calcium and phosphate ions. Scaglione [13] in 1956 reported that a patient with abnormally low phosphatase activity in bone might nevertheless have normal phosphatase activity in liver, duodenal juice, and indeed, in a tissue culture of osteoblasts. In 1958 Kretzmer and associates [14] reported alkaline phosphatase absent from the leukocytes of a patient and normal in those of the mother (whose serum phosphatase concentration was low).

#### CLINICAL DEFECTS

The clinical findings in hypophosphatasia are probably all attributable to the defect in formation of true bone to premature synostosis of the skull or to the hypercalcemia which is a frequent but not constant feature. Since the essential feature of the generalized bone disease is inadequacy of mature bone formation the clinical manifestations are more severe the earlier the appearance of the disorder. When it appears in utero infants are often stillborn and lack adequate bony support for cranial and thoracic cavities. When it appears in adult life, patients may be asymptomatic or have only symptoms attendant upon an occasional fracture. The disease of bone induces the gross changes of true rickets with beading of costochondral junctions, bowing of the legs and widening of the ends of long bones. Figure 44-1 shows the epiphysis of a child of 39 months with hypophosphatasia. The premature synostosis may be anticipated in infancy by the absence of radiologically demonstrable bone over large areas of skull giving the appearance of wide sutures separating plaques of bone. As in the syndrome of oxycephaly or acrocephalosyndactyly [15, 15a] these areas represent in fact uncalcified osteoid without fibrous septums [16]. As they calcify exophthalmos

junction of a child with the disorder [9]. The defect in appositional and subperiosteal bone formation appears as wide zones of uncalcified osteoid lined with osteoblasts. There is virtually no osteoclasts nor is there fibrosis of the marrow or other evidence of bone destruction. As in osteomalacia, the total mass of bone plus matrix may appear greater than normal [16]. The defect in membranous bone which may be so extensive as to leave only plaques of true bone in the skull [1] is histologically comparable, showing wide areas of uncalcified osteoid. It has been observed that the true bone in this disease may have a microradiologic structure relatively primitive for the patient's age and that the collagen fibrils may be correspondingly poorly arranged [20]. Material from patients with true rickets of comparable degree and severity is not available for comparison. It may be that the primitive structure results from the relative absence of remodeling of osteoid as compared with that in true bone. The first step in remodeling is, of course, bone destruction which is indicated histologically by the presence of osteoclasts. Osteoclasts are extremely rare in the bones during active rickets or osteomalacia.

### CALCIFICATION PROCESS

It is not known how the biochemical defects (decreased serum alkaline phosphatase activity, elevated plasma and urine phosphoethanolamine levels, and occasionally elevated serum and urine calcium concentration) are interrelated. The disorder may be better understood in the light of current concepts of bone physiology.

Bone formation begins with the deposition of matrix in apposition to preexisting bone or calcified cartilage or with its formation *de novo* in intramembranous sites. The osteoid is deposited by osteoblasts which contain alkaline phosphatase. Some alkaline phosphatase from osteoblasts is liberated into the circulating fluids. In the absence of liver disease, the serum alkaline phosphatase concentration closely parallels and serves as an index of the number and activity of osteoblasts.

Deposition of mineral in osteoid probably begins with the formation of an initial complex of calcium and phosphorus which in all probability is  $\text{CaHPO}_4$  [21]. The formation of this complex depends in part upon the activity product of  $\text{Ca}^{++} \times \text{HPO}_4^{--}$  surrounding the osteoid and in part upon the structure of the osteoid itself. Once formed, it is spontaneously rearranged at physiologic pH to the hydroxyapatite structure of bone. Experimental evidence regarding the essential ion product has been derived largely from studies with rachitic cartilage. It is assumed, without good evidence, that calcification of osteoid follows the same principles. Calcification does not appear in rachitic cartilage incubated in solutions with a solubility product below a critical figure. The same applies, of course, to solutions of calcium phosphate alone. The important

first in adult life with no evidence of earlier disease. It thus appears that spontaneous, virtually complete remissions may occur and that new manifestations may not appear for a number of years.

#### LABORATORY DIAGNOSIS

Laboratory diagnosis consists of (1) demonstration of serum alkaline phosphatase values below normal for the patient's age, (2) histologic characterization of the bone lesion, (3) demonstration of phosphoethanolamine in the urine. This compound has not been identified in

Fig. 44-2 Costochondral junction of a rib of a 33-month-old girl with hypophosphatemia. Note disorganization of cartilage and osteoid seams lined with osteoblasts. Undecalcified. (By permission of Dr. Edna Sobel.)

the urine of normal subjects. Quantitative data for phosphoethanolamine in urine or plasma in hypophosphatemia are not yet available.

Chemical analysis may also allow the recognition of hypophosphatemia in persons with no signs or symptoms of the disease. Relatives of patients may have low serum alkaline phosphatase values and phosphoethanolamine in the urine (see below). These persons presumably are heterozygous for hypophosphatemia.

The histologic picture is generally indistinguishable from that of true rickets. The defect in ossification from cartilage appears as in rickets, as a widening of the zones of provisional calcification, disruption of the normal columnar arrangement of cells, and failure of calcification of degenerating cartilage. Figure 44-2 shows a section from a costochondral

phatase in the calcification process however since it has been shown that beryllium has this property in concentrations which do not affect liberation of inorganic phosphate from  $\beta$  glycerophosphate [27]

Finally it has been suggested that phosphatase serves to destroy phosphate esters which inhibit calcification as crystal poisons [28] In this view, the phosphate esters which are promoting calcification in slice experiments 'protect' phosphate-containing sites from phosphatase leached from the slices [21]

## BIOCHEMICAL DEFECTS IN HYPOPHOSPHATASIA

Although rachitic cartilage (and probably the uncalcified osteoid in osteomalacia) normally calcifies readily in normal concentrations of calcium and phosphate ions this does not occur in patients with hypophosphatasia. In this syndrome the serum phosphorus level is normal and the serum calcium level is frequently elevated despite the presence of histologic rickets. Furthermore Fraser showed directly that rachitic cartilage would calcify in the serum of a patient with hypophosphatasia. This makes it unlikely that the defect in calcification results from too low an activity product of circulating calcium and phosphate ions. The possibility does exist however that calcium may be present in a complexed nonionized form. This is suggested by the observation that vitamin D in average doses may rapidly elevate the serum calcium concentration of patients with hypophosphatasia [9]. Anning and associates [9] showed that vitamin D can increase significantly the concentration of diffusible nonionized calcium. On the other hand if calcification depends upon the activity of phosphate locally at osteoid sites and this is dependent upon phosphatase the disorder may indeed involve a decrease of effective ion product.

The syndrome thus provides strong clinical evidence that alkaline phosphatase plays a role in the calcification process. Since osteoid is present in abundance it appears likely that phosphatase is not required for its formation. There remains the possibility that osteoid formed without alkaline phosphatase is abnormal e.g. lacks a phosphorus-containing compound required for *in vivo* calcification such as the mucopolysaccharide described by DiStefano and associates [30]. As noted above the rachitic cartilage of a patient with hypophosphatasia did not calcify in normal serum [12]. Attempts to define further the relationship between the enzyme deficiency and the bone disease have proved unsuccessful.

An inhibitor of alkaline phosphatase could not be found in the serum of patients although carefully sought for by four groups of investigators [9 10 16 20]

point is that calcification *in vivo* normally occurs despite a product of activities of  $\text{Ca}^{++} \times \text{HPO}_4^{--}$  in serum below that required for spontaneous precipitation (Hydroxyapatite the mineral phase of formed bone will remove calcium and phosphate from solutions with activity product  $\text{Ca}^{++} \times \text{HPO}_4^{--}$  below that of serum. The present problem however, concerns a failure of calcification *de novo* of newly formed osteoid or "calcifiable" cartilage.)

A number of attempts have been made to explain this paradox. The first attempt (which antedated indeed accurate knowledge of the appropriate activity products) was that of Robison [22] who noted the presence of alkaline phosphatase in all areas where calcification occurs. He suggested that phosphatase acts to liberate inorganic phosphate at the site of calcification and thus by raising the activity product of calcium by phosphate ions locally, to initiate crystallization. This view was strengthened by the observation that calcification of rachitic cartilage would not occur after inactivation of phosphatase, save at concentrations of calcium and phosphate ions far above the physiologic range [23]. The concept was rendered untenable, however by the demonstration that inhibitors of glycolysis not affecting alkaline phosphatase could inhibit calcification of cartilage in concentrations of calcium and phosphate well above the physiologic range. It was shown that calcification is blocked by phlorizin, iodoacetate or fluoride but that it can be restored in the presence of the first two if glucose 1 phosphate or 3 phosphoglycerate respectively, is added. These compounds appear "below" the block in glycolysis. ATP itself would not promote calcification so it does not appear that the glycolytic cycle serves solely to supply energy [24].

Further this inhibition can be overcome by the addition of substrates (such as phenylphosphate) not in the pathway of glycolysis but readily hydrolyzed by phosphatase. These observations led Gutman and Yu to propose that phosphatase acts as a transferase of phosphate from organic phosphate esters to available sites on the matrix [24].

Two other theories have been proposed to explain the place of phosphatase in bone formation. It has been suggested that it has no direct role in calcification but is associated with formation of organic matrix. This view finds strong support in the recent demonstration that calcification of cartilage reconstituted from solution will occur spontaneously at physiologic concentrations of calcium and phosphorus [25]. The only requirement is that the cartilage (whatever the source) have the structure of 'native' cartilage. This poses the question as to why all native cartilage does not calcify. It has been suggested that traces of an essential mucopolysaccharide [26] are present even in these purified solutions. It has been shown that beryllium which inhibits alkaline phosphatase activity inhibits calcification. This does not establish a role for phos-

phatase in the calcification process however since it has been shown that beryllium has this property in concentrations which do not affect liberation of inorganic phosphate from  $\beta$  glycerophosphate [27]

Finally it has been suggested that phosphatase serves to destroy phosphate esters which inhibit calcification as crystal poisons [28] In this view the phosphate esters which are promoting calcification in slice experiments protect phosphate-containing sites from phosphatase leached from the slices [21]

## BIOCHEMICAL DEFECTS IN HYPOPHOSPHATASIA

Although rachitic cartilage (and probably the uncalcified osteoid in osteomalacia) normally calcifies readily in normal concentrations of calcium and phosphate ions this does not occur in patients with hypophosphatasia In this syndrome the serum phosphorus level is normal and the serum calcium level is frequently elevated despite the presence of histologic rickets Furthermore Fraser showed directly that rachitic cartilage would calcify in the serum of a patient with hypophosphatasia This makes it unlikely that the defect in calcification results from too low an activity product of circulating calcium and phosphate ions The possibility does exist however that calcium may be present in a complexed nonionized form This is suggested by the observation that vitamin D in average doses may rapidly elevate the serum calcium concentration of patients with hypophosphatasia [9] Arning and associates [29] showed that vitamin D can increase significantly the concentration of diffusible nonionized calcium On the other hand if calcification depends upon the activity of phosphate locally at osteoid sites and this is dependent upon phosphatase the disorder may indeed involve a decrease of effective ion product

The syndrome thus provides strong clinical evidence that alkaline phosphatase plays a role in the calcification process Since osteoid is present in abundance it appears likely that phosphatase is not required for its formation There remains the possibility that osteoid formed without alkaline phosphatase is abnormal e.g. lacks a phosphorus-containing compound required for *in vivo* calcification such as the mucopolysaccharide described by Dr Stefano and associates [30] As noted above the rachitic cartilage of a patient with hypophosphatasia did not calcify in normal serum [12] Attempts to define further the relationship between the enzyme deficiency and the bone disease have proved unsuccessful

An inhibitor of alkaline phosphatase could not be found in the serum of patients although carefully sought for by four groups of investigators [9 10 16 20]

point is that calcification *in vivo* normally occurs despite a product of activities of  $\text{Ca}^{++} \times \text{HPO}_4^{--}$  in serum below that required for spontaneous precipitation (Hydroxyapatite the mineral phase of formed bone will remove calcium and phosphate from solutions with activity product  $\text{Ca}^{++} \times \text{HPO}_4^{--}$  below that of serum. The present problem however, concerns a failure of calcification *de novo* of newly formed osteoid or calcifiable cartilage.)

A number of attempts have been made to explain this paradox. The first attempt (which antedated indeed, accurate knowledge of the appropriate activity products) was that of Robison [22] who noted the presence of alkaline phosphatase in all areas where calcification occurs. He suggested that phosphatase acts to liberate inorganic phosphate at the site of calcification and thus, by raising the activity product of calcium by phosphate ions locally to initiate crystallization. This view was strengthened by the observation that calcification of rachitic cartilage would not occur after inactivation of phosphatase save at concentrations of calcium and phosphate ions far above the physiologic range [23]. The concept was rendered untenable, however by the demonstration that inhibitors of glycolysis not affecting alkaline phosphatase could inhibit calcification of cartilage in concentrations of calcium and phosphate well above the physiologic range. It was shown that calcification is blocked by phlorizin, iodoacetate or fluoride but that it can be restored in the presence of the first two if glucose 1 phosphate or 3 phosphoglycerate respectively is added. These compounds appear "below" the block in glycolysis. ATP itself would not promote calcification so it does not appear that the glycolytic cycle serves solely to supply energy [24].

Further, this inhibition can be overcome by the addition of substrates (such as phenylphosphate) not in the pathway of glycolysis but readily hydrolyzed by phosphatase. These observations led Gutman and Yu to propose that phosphatase acts as a transferase of phosphate from organic phosphate esters to available sites on the matrix [24].

Two other theories have been proposed to explain the place of phosphatase in bone formation. It has been suggested that it has no direct role in calcification but is associated with formation of organic matrix. This view finds strong support in the recent demonstration that calcification of cartilage reconstituted from solution will occur spontaneously at physiologic concentrations of calcium and phosphorus [25]. The only requirement is that the cartilage (whatever the source) have the structure of native cartilage. This poses the question as to why all native cartilage does not calcify. It has been suggested that traces of an essential mucopolysaccharide [26] are present even in these purified solutions. It has been shown that beryllium which inhibits alkaline phosphatase activity inhibits calcification. This does not establish a role for phos

### THE RAPY

There is no generally accepted therapy for hypophosphatemia. Vitamin D has been tried (because the bone disease is the same as that found in rickets) with apparent improvement in one case [17]. This same case and several other cases so treated [2, 9, 36] developed hypercalcemia and signs of vitamin D intoxication. There is no further evidence that vitamin D deficiency plays a part in the disease or that therapy with vitamin D is effective.

In a single case, cortisone has been reported to produce rapid improvement in the radiologic defects in the bones and to raise the serum alkaline phosphatase concentration to twice pretreatment values, although not to normal levels. Relapse occurred when cortisone was omitted and there was a comparable response when it was reintituted. On the other hand, four cases are said to have shown no response to cortisone [18, 37-39].

There is no record of the use of phosphate supplements as a therapeutic measure to induce hyperphosphatemia. As noted above, it is possible that acalification in hypophosphatemia results from a subnormal ion product at osteoid sites normally overcome through an action of phosphatase. It is possible that the defect could be overcome by inducing an abnormally high solubility product in circulating fluids.

### GENETIC ASPECTS

Figure 43-3 shows the family tree given by McCance and associates [16] who studied two siblings who died in infancy. It is of interest that low serum alkaline phosphatase values were found in two generations. There was strong circumstantial evidence for the occurrence of hypophosphatemia in the maternal sibship of the father of the propositi.

An analysis of the genetic aspects of hypophosphatemia by Steinberg is quoted in a recent review [3]. He estimates that the incidence of the disease among siblings of probands is 23 per cent, notes no evidence of sex linkage, and finds significantly more affected females than males. From data based on serum phosphatase values alone, he makes the following analysis. The serum phosphatase level is low in 70 per cent of affected parents for whom data are available. Assuming that the disease is transmitted as an autosomal recessive trait (and that all parents of patients are thus heterozygotic for hypophosphatemia), two-thirds of all clinically normal siblings of patients should be heterozygotic and about 50 per cent ( $0.70 \times 0.66$ ) should then have low serum phosphatase values. This compares well with an observed ratio of three affected in seven clinically healthy siblings tested. Steinberg further noted a high frequency of the disease in the last born sibling and concludes that it is

Phosphoethanolamine has been isolated from urine and plasma of patients and of some parents of patients. Although alkaline phosphatase readily hydrolyzes this ester, there is no reasonable explanation for the association of the two biochemical defects in the disease. It has been suggested that phosphoethanolamine is the true substrate for bone alkaline phosphatase [19]. Thus, a hereditary block in the reaction

would lead to an excess of plasma and urinary phosphoethanolamine. A block in hydrolysis of the ester could lead to a defect in calcification whether the phosphatase acts as a liberator of inorganic phosphate as a transferase or indeed, as a metabolic "poison" as suggested by Neuman [28]. There is no evidence in favor of or against such a hypothesis. Phosphoethanolamine is not normally found in serum or urine. It is a normal constituent of brain tissue. It may appear with amino acids in the urine of patients with liver disease [31], celiac disease and erythroblastosis fetalis [32].

Hypercalcemia and hypercalciuria occur frequently but not constantly in hypophosphatasia. When they do occur there may be nitrogen retention and nephrocalcinosis. A serum calcium concentration greater than 11 mg per 100 ml was noted on one or more occasions in 20 of the 31 cases for whom data were available [2].

It has been observed [1] that the serum calcium may undergo wide fluctuations without apparent cause and [2] that hypercalcemia may result from therapy with moderate doses of vitamin D. It may also occur in subjects who have never received vitamin D [3]. Thus one patient developed a serum calcium concentration of 17 mg per 100 ml after 10 days on 50 000 units a day [9], another who had a serum calcium concentration of 12 to 15 mg per 100 ml before therapy with the vitamin showed a return of serum calcium level to normal while the patient was receiving 50 000 units a day [17].

Inasmuch as the bones are surrounded with osteoid and little or no osteoclastic activity is seen histologically it has been generally assumed that the hypercalcemia results from hyperabsorption of calcium. Even with normal calcium absorption hypercalcemia might indeed develop if the bone matrix were unable to deposit calcium (as is apparently the case in hypophosphatasia). The occurrence of all the other abnormalities of hypophosphatasia in many patients with normal serum calcium who have not had vitamin D throughout their clinical course eliminates the possibility that the alkaline phosphatase in this disease is depressed as a result of hypervitaminosis D and hypercalcemia [33-34].

activity is decreased and phosphoethanolamine is found in plasma and urine. There may be premature synostosis of the cranial vault, hypercalcaemia, nephrocalcinosis and premature loss of teeth.

2 The disease may be detected first in infancy or in adulthood. Diagnosis is based on the demonstration of radiologic and histologic changes in bone indistinguishable from those of rickets, phosphoethanolamine in the urine and decreased serum alkaline phosphatase activity.

3 The cardinal pathologic feature is inadequate calcification of bone matrix. The biochemical basis for this and its relation to the other biochemical defects are not known. It is possible that alkaline phosphatase is necessary for the formation of normal osteoid or that phosphoethanolamine normally has an integral place in the calcification process.

4 The disease picture offers strong support for a role for alkaline phosphatase in normal calcification of bone.

5 There is no adequate therapy.

6 Available data suggest that the disease is inherited as an autosomal recessive trait. Heterozygotes may have low serum alkaline phosphatase concentration, high urinary excretion of phosphoethanolamine or both without bone disease.

possible that heredity may not be involved in the disease. It may be of course that families with an affected child avoid future pregnancies or that medical reports appear before the families are complete.

The analysis on which Steinberg's study was based does not include more recent data on phosphoethanolamine excretion among ancestors and siblings of patients. When this valuable adjunct to the detection of heterozygosity is incorporated into a larger genetic study the hereditary

aspects of hypophosphatasia should be considerably clarified [2]. Fraser reported that this test brought the incidence of detectable heterozygosity in parents of patients to 81 per cent. He notes that there is no good evidence that the defect of phosphatase and that of phosphoethanolamine metabolism are carried on the same gene and that there is suggestive evidence that they are not. Relatives who excrete phosphoethanolamine tend to have higher serum phosphatase values than those who do not.

## SUMMARY

1 Hypophosphatasia is a familial disease in which severe skeletal defects result from a failure of deposition of apatite in the end and of normal ossification at epiphyseal plates. The serum alkaline phosphatase

## Chapter 45

### Hereditary Hypoproteinemias and Other Plasma Protein Abnormalities

---

*Robert S. Gordon, Jr.*

During the past decade the availability of isotopic tracers and the application of the concept of the dynamic state of body constituents [1] together with increasingly effective procedures for the determination and isolation of specific proteins [2] have led to significant advances in the understanding of the physiology and biochemistry of the plasma proteins. At the same time improved clinical chemical methods for the estimation of proteins and the great simplification of electrophoresis by the introduction of supporting media have stimulated the application of this new knowledge to the study of disease [3]. It is not surprising therefore that this decade has been the period of discovery of disorders characterized by abnormal metabolism of plasma proteins. Some of the important defects in plasma protein metabolism will be discussed in this chapter. In these conditions deficiency or qualitative abnormality of the plasma protein is demonstrable by physical methods.

Before the disorders of plasma protein metabolism are introduced it will be desirable to outline the normal metabolism of these constituents. No plasma protein has been so extensively studied with regard to origin, turnover and metabolic fate as albumin. Its natural abundance, relatively high stability, the fact that it may be purified by crystallization and the availability of large quantities for intravenous administration to man make it particularly suitable for metabolic investigations. For these reasons its metabolism will be discussed as an example of plasma protein turnover. Far less is known of the turnover of the other plasma proteins although it seems reasonable to assume that their metabolism is similar to that of albumin with different rates of formation and destruction or utilization. Gamma globulin has been shown to differ from albumin in one important respect: it originates in peripheral tissues [4] probably in

with an amino acid sequence that appears to deviate from the normal only with regard to a small number of residue but in which the deviant synthesis is itself specific and is passed on unchanged from generation to generation.

### *Distribution and Catabolism of Albumin*

The distribution of serum albumin in man has been shown [16-17] to involve a volume considerably greater than that of the circulating plasma. The latter contains only about 40 per cent of the total exchangeable albumin. The presence of plasma proteins in lymph was emphasized many years ago by Drinker and Lield [18] and the existence of immunologically identifiable plasma proteins in the interstitial fluid of muscle has been shown by Gitlin, Landing, and Whipple [19]. Albumin degradation appears to be a first-order process and a newly synthesized molecule is just as likely to be degraded as an old one. A semilogarithmic plot of the disappearance of labeled albumin yields a straight line, and the survival of the protein is measured by a half time.

A recent study of the degradation of  $I^{125}$  labeled albumin in man [20] indicates that the site of the metabolism of albumin is an extravascular compartment which is in rapid equilibrium with the circulating albumin. Animal experiments [21] suggest that the liver plays an important role in the catabolism as well as in the synthesis of albumin *in vivo* and studies *in vitro* with surviving perfused liver [22] and with slices [23] demonstrate hepatic albumin degradation. The further fate of compounds released by the degradation of albumin *in vivo* is not known although it has been shown in the intact animal that labeled amino acids from albumin eventually make their way into new proteins [24-25]. Albright et al. [26] and Waterhouse, Bassett, and Holler [27] suggest that albumin contributes to the formation of new protoplasm in human subjects. In balance studies on subjects receiving albumin by vein they find retention of phosphorus which so far exceeds the retention of calcium that it cannot all be accounted for by bone formation.

### *Clinical Investigation of Albumin Metabolism*

Luck [28] has described in sobering detail the problems confronting the clinical investigator of serum protein turnover. An isotopically labeled protein is introduced into the circulation of the subject to be investigated and its rate of disappearance is followed. The performance of such a study is complicated from the start by the difficulties inherent in the isolation of a pure protein for administration and for isotopic assay. Other difficulties are inherent in the biologic behavior of the labeled protein. If it is tagged with  $N^{15}$ ,  $C^{14}$  or  $S^{35}$  the commonly used isotopes of the elements

plasma cells [6]. In addition, most of the plasma proteins cannot be isolated as single components for investigation. The heterogeneity of  $\gamma$  globulin as usually defined seems to be reflected in a range of half times in survival studies [6].

## METABOLISM OF SERUM ALBUMIN

### *Chemistry of Albumin*

Serum albumin in crystalline form has been available for chemical investigation since the work of Cohn, Hughes, and Weare [7] in 1947. The studies that have been performed on this protein have made it by far the best known of the plasma proteins, although its detailed structure has not yet been defined. It probably consists of a single peptide chain, internally cross-linked by disulfide bonds between cysteine residues [8]. The terminal amino acids have been tentatively identified for human serum albumin: the N-terminal residue is aspartic acid [9, 10], followed by alanine. The C-terminal acid is leucine, with (albumin) glycine valine alanine leucine being the probable sequence of preceding residues [11]. A discussion of the many physical characteristics and chemical properties of serum albumin that have been reported is beyond the scope of this chapter and is not essential for the present consideration of disturbances in its metabolism. Edsall and Wyman [12] have incorporated the significant features of the physical chemistry of serum albumin into their recent monograph.

### *Synthesis of Albumin*

Beyond the observation that incorporation of  $C^{14}$  lysine into serum albumin occurs exclusively in the liver of the rat [13], virtually nothing is known of the details of its synthesis. The processes of protein synthesis and their genetic control have been intensively investigated in systems simpler than mammalian liver; this field has been reviewed recently by Anfinsen [14].

The question of the specificity of protein synthesis and structure is of the greatest importance in a discussion of the disorders of serum protein metabolism. In a current review of this field, Vaughan and Steinberg [15] advance the belief that all the proteins that have been adequately characterized are synthesized by mechanisms of high specificity, so that each molecule of the protein under consideration is identical with each other, at least as regards amino acid sequence. This tenet is supported by the apparent homogeneity throughout a wide variety of studies of human and bovine serum albumins, even when the proteins are prepared from pooled serums representing many individuals. This concept of specificity of chemical structure of the protein renders intelligible the investigations of the hereditary variation discussed below, in which an albumin occurs

## ABNORMALITIES OF SERUM ALBUMIN METABOLISM

## DOUBLE ALBUMIN ANOMALY (BISALBUMINEMIA)

This condition which cannot properly be called a disease has been described in at least six kindreds within the past 25 years. Since the abnormality can be detected only by electrophoretic analysis of the plasma proteins and since it appears to produce no untoward effects in its bearers, it is hardly surprising that it had not come to medical attention earlier. As an inherited trait which can be measured quantitatively, it is of interest to the geneticist, and familiarity with the condition may prevent unnecessary excitement on the part of physicians who encounter the anomaly in the future. It seems appropriate to mention it in connection with other disorders of plasma protein metabolism.

The first mention of the anomaly was made by Scheurlen [30] who noticed a double albumin peak in the electrophoretic diagram of the plasma proteins of one of a series of diabetic patients. This case may actually not have been typical since the separation of the two peaks in the electrophoretic diagram appears to have varied with changes in the clinical condition of the patient. In a later report [36] it is stated that the same anomaly was encountered in two relatives of this original patient and the anomaly is equated by the authors with more clear-cut examples of the disorder. Subsequent reports by Knedel [37-38], Nennstiel and Becht [39], Earle, Hutt, Schmid and Gitlin [40-41] and by Bennhold, Ott and Scheurlen [36] have brought to six the number of kindreds in which the condition is recognized. The family studied by Earle et al. is the largest, containing 20 proved and 3 presumed cases. These authors have carried out studies of the pattern of heredity and of the chemistry of the abnormal protein. The discussion which follows is based primarily on their observations.

*Biochemical Features of Albumin II*

The anomaly consists of a double albumin peak in the electrophoretic pattern of serum. The combined areas are equal to the area of a normal albumin component. The faster moving component has the mobility of normal albumin and cannot be differentiated from it; the slower moving component (called albumin B by Earle et al.) is superimposed on the  $\alpha_1$  globulin. The two albumins do not separate in the ultracentrifuge, are both found in Cohn fraction V, and become equal in electrophoretic mobility at pH values above 11.3 and below 3.5. The quantitative precipitation reaction with rabbit antiserum and the Ouchterlony agar diffusion technique do not differentiate albumin II from normal human serum albumin. These observations may be explained satisfactorily by the hypothesis that albumin B is in fact identical with normal serum albumin.

naturally occurring in proteins the investigator must estimate the extent to which these isotopes liberated by the breakdown of body or plasma protein may be reutilized in the synthesis of new protein. If, on the other hand, it bears  $I^{131}$  the most commonly employed extraneous isotopic label there is the ever present possibility that the labeled molecules may be differentiated metabolically from the natural ones. These considerations make it impossible to obtain an absolutely precise measurement of the rate of albumin turnover in man but they detract only slightly from the usefulness of labeled proteins in the study of clinical problems associated with disturbed albumin metabolism. By applying the same procedure to subjects under study and to normal controls one can at least make a valid estimate of the direction and extent of the differences encountered.

In the procedure of Armstrong et al [29-30], the patients label their own proteins after ingestion of isotopic precursors contained in yeast grown in the presence of  $S^{34}$ . The rates of incorporation and loss of isotope from the circulating plasma proteins can then be followed. It is apparent that this technique does not permit the calculation of total body albumin content by isotope dilution. A further disadvantage stems from the labeling of all body proteins and in fact all sulfur compounds undergoing active metabolism so that there is a very considerable pool of isotope available for reincorporation into plasma proteins as it is released. For this reason, the absolute rates of catabolism of albumin estimated by this procedure are erroneously low, but the procedure is a simple one, and probably suitable for the comparison of patients with control subjects. Many of the objections that might be raised to the above mentioned procedure were avoided by Volwiler et al [31], who administered isotopic methionine to one subject and then transferred labeled plasma proteins from this subject to others whose turnover rate was to be investigated. Unfortunately this procedure is too cumbersome for widespread clinical use and involves hazards (of radiation for the plasma donor and hepatitis for the recipient) that sharply limit its applicability.

In contrast to the techniques just described which use isotopes of atoms naturally occurring in proteins the most popular procedure [16-17-20] has been the study of albumin distribution and degradation using protein labeled with  $I^{131}$ . Cohen et al [32] and Campbell et al [33] have presented evidence that  $I^{131}$  labeled protein behaves very much like  $C^{14}$  protein in experimental animals and a recent study by Freeman et al [34] demonstrates that  $I^{131}$  albumin and native albumin are degraded at the same rate in a patient with analbuminemia. The easy availability of  $I^{131}$  albumin, the simplicity and accuracy of its assay and the advantages of the isotope in minimizing radiation hazard to the patient have made this compound a favorite tool for clinical research.

kindreds 13 of 18 have the anomaly. When one remembers that there are necessarily 6 affected propositi it may be seen that the probability of inheriting the trait from an affected parent is not significantly different from 0.5. The data are interpreted by Finkle et al. as consistent with the hypothesis that there are two genetic loci controlling the synthesis of albumin that these loci are independent and that in the heterozygote there is equal production of normal albumin and albumin B. These authors consider that the anomaly is transmitted as a codominant characteristic both the abnormal and the normal genes being fully expressed. The homozygotic abnormal situation has not been encountered to date. Whether or not such a homozygotic individual would suffer from some clinically detectable disease cannot be predicted on the basis of presently available information.

### ANALBUMINEMIA

#### *Historical Aspects*

Bennhold Peters and Roth [42] first described a pair of siblings from whose plasma albumin was absent. Subsequent communications from the clinic at Tübingen [43-44] have amplified the original description and presented the results of a variety of biochemical investigations. Recently three more analbuminemic subjects have been reported: two in the United States and one in Switzerland [45-47]. The former two patients have been under observation since 1952 and 1956 respectively; the latter was only recently discovered. Pending the identification of more individuals with this disorder the description of the disease must be based on this small series and generalizations must be regarded as tentative.

#### *Clinical Features*

The most striking feature of analbuminemia is the relative paucity of symptoms and signs. Edema, usually of mild degree, has been noted in all cases but one and has been relieved by the administration of albumin in the two individuals who received full replacement doses. The significance of edema cannot be assessed in the patient reported by Shetlar et al. [47] because of the coincident occurrence of congestive heart failure. Two subjects [44, 45] have received replacement therapy with large amounts of exogenous human serum albumin and have noted an increased sense of well-being which may be taken as evidence of a preexisting mild malaise. The two young male patients, however, feel well enough to carry on heavy manual labor [43, 46]. Bennhold and his colleagues [42] observed that their two patients with analbuminemia had a moderate degree of arterial hypotension, a feature which they considered to be an adaptation which helps to prevent excessive edema for

except that two or more cysteine or tyrosine residues replace residues of dicarboxylic acids in the structure of the molecule

Individuals who have the albumin II anomaly quite uniformly have approximately equal quantities of normal albumin and of albumin B. Earle et al state that albumin II constitutes  $57 \pm 4.4$  per cent of the total albumin. The failure of electrophoresis to separate albumin B from  $\alpha_1$  globulin necessarily introduces a systematic error into this estimate.

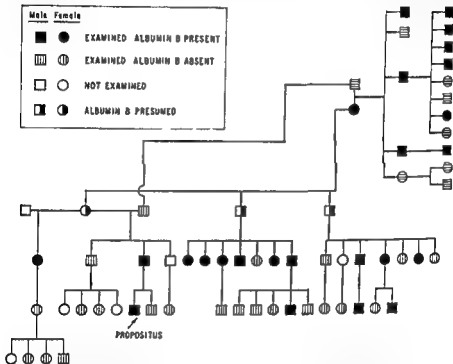

Fig 45-1 Genealogy of double albumin anomaly (Redrawn after Earle et al [40])

The authors feel that a correction for the average amount of  $\alpha_1$  globulin would make the quantities of the two albumins virtually identical in all their cases. As yet no study of the relative turnover rates of the two albumins has been effected.

### Genetics

The pattern of heredity may be fairly clearly defined from the accounts of double albumin anomaly which have been published. The genealogy of the family studied by Earle et al is reproduced in Fig 45-1. Since there is no known case in which the anomaly was found in the offspring of unaffected parents, it may be presumed that only the offspring of an affected parent are exposed to genetic risk. In the family studied by Earle et al, 28 of 46 individuals at risk are affected; in the other 5

hundreds 13 of 18 have the anomaly. When one remembers that there are necessarily 6 affected propositi it may be seen that the probability of inheriting the trait from an affected parent is not significantly different from 0.5. These data are interpreted by J. Lurie et al. as consistent with the hypothesis that there are two genetic loci controlling the synthesis of albumin that these loci are independent and that in the heterozygote there is equal production of normal albumin and albumin B. These authors consider that the anomaly is transmitted as a codominant characteristic both the abnormal and the normal genes being fully expressed. The homozygotic abnormal situation has not been encountered to date. Whether or not such a homozygotic individual would suffer from some clinically detectable disease cannot be predicted on the basis of presently available information.

### AN ALBUMINEMIA

#### *Historical Aspects*

Bennhold Leters and Roth [42] first described a pair of siblings from whose plasma albumin was absent. Subsequent communications from the clinic at Tübingen [43-44] have amplified the original description and presented the results of a variety of biochemical investigations. Recently three more analbuminemic subjects have been reported, two in the United States and one in Switzerland [45-47]. The former two patients have been under observation since 1952 and 1956 respectively; the latter was only recently discovered. Pending the identification of more individuals with this disorder, the description of the disease must be based on this small series and generalizations must be regarded as tentative.

#### *Clinical Features*

The most striking feature of analbuminemia is the relative paucity of symptoms and signs. Edema, usually of mild degree, has been noted in all cases but one and has been relieved by the administration of albumin in the two individuals who received full replacement doses. The significance of edema cannot be assessed in the patient reported by Shetlar et al. [47] because of the coincident occurrence of congestive heart failure. Two subjects [44-45] have received replacement therapy with large amounts of exogenous human serum albumin and have noted an increased sense of well-being which may be taken as evidence of a preexisting mild malaise. The two young male patients, however, feel well enough to carry on heavy manual labor [43-46]. Bennhold and his colleagues [42] observed that their two patients with analbuminemia had a moderate degree of arterial hypotension, a feature which they considered to be an adaptation which helps to prevent excessive edema for

mation Of the three patients reported recently, one has normal blood pressure [50] one has a possibly slightly reduced value [46] and one [47] having aortic insufficiency cannot be considered in this respect

Associated disorders or abnormalities are present in several of these analbuminemic subjects, but these features each existing in only one case, cannot be considered an integral part of the picture of albumin deficiency The patient reported by Shetlar et al [47] suffers from rheumatoid arthritis of severe degree and from aortic valvular insufficiency leading to congestive heart failure He had sought medical aid for these conditions, and the analbuminemia was an incidental discovery The patient studied by Bartter and collaborators [50] suffers from the deformities typical of progressive lipodystrophy and has required surgical treatment for varicose veins The subject seen by Beck and Dorta [46] gave a history of cranial injury in childhood and subsequent convulsive episodes, he also was noted to have atrophic testes and a mild degree of feminization He had developed a dermatitis from handling cement and had sought medical attention for that disorder

The generally good health enjoyed by these patients in spite of their analbuminemia makes it impossible to assign an age of onset to the condition In four of the five subjects the anomaly was documented during young adult life and three of the five had been followed for over 6 years with no essential alteration in the condition It therefore seems likely that analbuminemia has been present since birth although the possibility that it is an acquired defect cannot be eliminated

### *Biochemical Aspects*

The term *analbuminemia* implies complete absence of serum albumin from the blood of these individuals The available evidence suggests that traces of albumin may be found by suitably exact methods but the quantities are so small that it seems justifiable to retain the present nomenclature The most thoroughly investigated subjects, from this point of view, are those at Tübingen In each of these, electrophoretic examination of serum revealed no albumin One subject was then treated with exogenous albumin the persistence of which makes other, more refined investigations impossible The other patient however, received no replacement therapy and has been reinvestigated more recently Lohss and Kallee [48] report the use of an elaborate procedure involving radioiodination immunologic precipitation and electrophoresis with the conclusion that if albumin is present the concentration must be less than 10 mg per 100 ml Later however Lohss and Ott [49] succeeded in demonstrating the presence of traces of albumin by immunoelectrophoresis Virtually identical findings are reported in the case of Beck and Dorta [46] although no albumin peak can be discerned on electrophoretic examination of whole serum immunoelectrophoresis in the

presence of an antialbumin serum reveals the presence of a trace of albumin. The case reported by Shetler et al. [47] was found to have less than 0.1 gm albumin per 100 ml serum with good agreement between results by electrophoretic and immunochemical methods. The case reported from the National Institutes of Health [48] had unfortunately been treated with exogenous albumin before any accurate measurements of serum albumin concentration were made.

The deficiency of serum albumin in analbuminemia can be attributed to failure of albumin production, not to an exaggerated rate of removal of albumin from the plasma. The disappearance of exogenous albumin administered to these subjects is indeed abnormally slow in the three instances in which it has been studied [44-47, 50]. In two instances the rate of removal of  $^{125}\text{I}$  labeled albumin has also been shown to be delayed [44, 45]. The failure of albumin production is not associated with other evidence of impaired liver function. The other plasma protein fractions are not decreased and in two cases [45, 47] liver biopsy has been carried out without the discovery of significant morphologic abnormalities. Beck and Dorta [46] performed a liver biopsy on their patient and assayed the tissue for a variety of enzymes. They noted a marked reduction in the activities of lactic malic and isocitric dehydrogenase and also decreased activity of glutamic-oxalacetic transaminase. The variability of their normal values for transaminase, however, is so great that this last finding is not clearly abnormal. They do not comment on morphology of the liver tissue.

Certain other biochemical abnormalities observed in the patients with analbuminemia may be considered to be effects, direct or indirect, of the lack of albumin. The concentration of serum globulins averages slightly above normal in the group, although no one component is strikingly increased. The results of laboratory procedures which depend upon serum protein concentrations (cephalin flocculation, thymol turbidity, Takata-Ura test) may be abnormal. The erythrocyte sedimentation rate is also uniformly elevated. Serum calcium concentration is reduced and there is a considerable increase in serum cholesterol, which was found to be as high as 610 mg per 100 ml in one instance [46] and over 400 mg per 100 ml in another [50]. In the two patients who have received adequate albumin replacement, these abnormalities have been corrected.

It is hardly possible to say that all the biochemical functions of serum albumin have been described. As the chief contributor to the colloid osmotic pressure of the plasma, albumin fulfills a role in the maintenance of physiologic relationships between intravascular and extravascular fluid volumes. Its vehicular function, suspected long ago by Bennhold [51], has been emphasized by recent studies of the binding of unesterified fatty acids by albumin [52] and the demonstration of the important role of this complex in the transport of fatty acids [53]. The patients with

analbuninemia are of great interest in so far as they demonstrate conclusively that neither these, nor any functions of albumin yet to be discovered are essential for life

### Treatment

Analbuninemia can be corrected in only one way—the infusion of sufficient human albumin to repair the defect (It is to be hoped that cases discovered in the future will be studied exhaustively before albumin

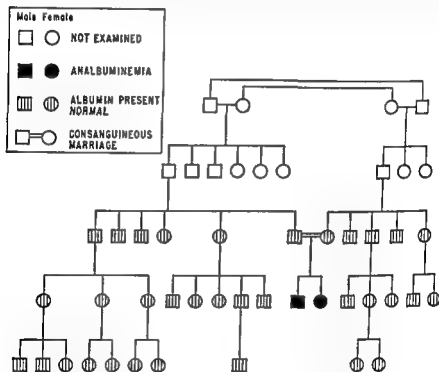

Fig 4-2 Genealogy of analbuninemia (Redrawn after Bennhold [49]) Symbols are the same as in Fig 45-1

supplementation is begun) The quantity of albumin required to maintain a reasonably normal blood level is in the range of 25 gm per week because of the slow degradation in these persons This amount can safely be tolerated in one infusion unless some associated condition presents a contraindication The advisability of instituting albumin treatment is not established on the basis of existing knowledge The mildness of the symptoms the apparently good prognosis and the availability of alternative means for the control of edema may be taken as arguments against the recommendation of costly and time consuming albumin treatment On the other hand the patients so treated appear to feel better and their

hypercholesterolemia which might contribute to the development of premature atherosclerosis is thereby corrected

### *Genetics*

A discussion of the pattern of inheritance of analbuminemia is not warranted at this time, since there are insufficient data to support any conclusion. There is no known example of transmission of analbuminemia from parent to offspring and the belief that it is a genetically determined anomaly is based solely on the existence of the condition in two siblings. The genealogy of these subjects has been published by Bennhold [43] and is reproduced in Fig 4a-2. It may be seen that these patients are the offspring of a consanguineous marriage so that there is a good possibility of an autosomal recessive pattern of inheritance. Beck and Dorta [46] suggest that there may also be some inbreeding in the ancestry of their patient although consanguinity between his parents was not known to exist. No other cases of analbuminemia have been found among his relatives [46] nor among the available relatives of the two American patients [47, 50].

## AGAMMAGLOBULINEMIA

### *Historical Aspects*

This disorder which has received considerable attention over the past 8 years was first described by Bruton in 1952 [54]. The pertinent literature has been reviewed by Good and Zak [55] and by Gitlin, Gross, and Janeway [56]; the latter presentation covers also the metabolism of this protein fraction and other diseases associated with abnormal serum concentrations. Agammaglobulinemia is customarily subdivided into congenital and acquired types. The former exists as the name implies from birth but is not manifest until passively transferred maternal  $\gamma$  globulin has been metabolized. Acquired agammaglobulinemia may develop at any age and in either sex; the distinction between the two forms in an individual patient is frequently impossible.

### *Metabolic Defect*

The metabolic defect in agammaglobulinemia consists of failure of  $\gamma$  globulin synthesis. The rate of degradation of  $\gamma$  globulin has been studied both with isotopic tracers [57-59] and by following the loss from the plasma of therapeutic doses of passively infused  $\gamma$  globulin [6, 50, 59]; it is not increased. Failure of antibody synthesis is not complete, however. In almost every case Gitlin et al [56] and Good and Zak [55] have been able to demonstrate small amounts of  $\gamma$  globulin by immunochemical procedures. In four cases studied at the National Institutes of Health [6] the serum contained small amounts of electrophoretically demon-

strable  $\gamma$  globulin. For this reason the term *agammaglobulinemia* is a misnomer but it is sanctioned by common use.

Agammaglobulinemia differs from an albuminemia in one important respect. While the liver in an albuminemia is morphologically intact the tissues of agammaglobulinemic subjects show a great deficiency or total absence of plasma cells. In addition, the lymph nodes are unusual in that they contain fewer lymphocytes than normal, and show ill-defined primary follicles [55, 60]. One may therefore suspect that the primary lesion in agammaglobulinemia is not solely a failure of the synthesis of one specific protein but that in some way it prevents the formation or maturation of the cells which should produce the protein. The condition might be considered closely allied to the familial structural malformations that have long been known to the anatomist.

### *Clinical Features*

The clinical manifestations of agammaglobulinemia are secondary to the failure of antibody synthesis and the resulting susceptibility to infection. Gitlin et al. [56] state that in their experience immunity to viral infections is not impaired but that the infections of agammaglobulinemic children are of bacterial origin. An interesting consequence of the lack of antibodies is that affected patients may not reject tissue homografts. Good and Varco [61] demonstrated the acceptance of a skin homograft in an agammaglobulinemic boy and this principle was employed therapeutically by Martin et al. [62] who transplanted lymph node tissue into an agammaglobulinemic adult. Subsequently there was immunochemical evidence of some renewal of antibody synthesis. Gitlin et al. [63] have pointed out the surprising fact that agammaglobulinemic subjects frequently develop the manifestations of rheumatoid arthritis or less often other collagen diseases. The significance of the occurrence of these conditions in patients who ought to be incapable of developing hypersensitivity is not yet known.

### *Diagnosis*

The diagnosis of agammaglobulinemia is established on the basis of chemical examination of the serum for  $\gamma$  globulin. Electrophoresis and immunochemistry are the methods most commonly employed for the definitive test. The condition should be suspected in any patient especially a male infant who manifests frequent bacterial infections and whose low resistance cannot readily be explained on any other basis. Since many such patients have repeated respiratory infections they may develop chronic pulmonary disease before the underlying condition is recognized. It is frequently possible to rule out agammaglobulinemia by the demonstration of normal blood type agglutinins. If these are absent in any but a type AB subject further examination of the serum

is indicated. Good and Tak [33] however note that an occasional agammaglobulinemic patient may have anti B agglutinin in his serum.

### Therapy

The accepted treatment for agammaglobulinemic patients consists of passive infusion of pooled normal human  $\gamma$  globulin combined with antibiotics to suppress infections. Present knowledge does not permit the prescription of a standardized program of therapy; treatment must be individualized. The antibiotics to be employed depend on the infecting organisms and their sensitivities.  $\gamma$  globulin should be administered intramuscularly in sufficient dosage to maintain a reasonable plasma level. No single therapeutically effective level can be established with certainty; the proper dosage must be ascertained empirically for each patient. A plasma  $\gamma$  globulin concentration of about 0.3 gm per cent is a reasonable initial goal; its achievement in an average 70 kg subject having no endogenous  $\gamma$  globulin will require a priming dose on the order of 25 gm protein. Maintenance of this level will require the administration of approximately 4 gm per week. The poor prognosis of untreated agammaglobulinemia can be considerably improved by careful management.

### Genetic Aspects

The acquired form of agammaglobulinemia is a sporadically occurring disease without known familial tendency. The congenital form on the

Fig. 4-3. Genealogy of congenital agammaglobulinemia. (Taken after G. H. L. [33]) Solid square = agammaglobulinemic male; open square = presumably affected—early death with history of recurrent severe bacterial infections. Open circle = presumably normal. The authors do not specify how many of these subjects were examined professionally.

other hand, appears to follow a definite genetic pattern. Diagnostic problems make the study of this condition difficult, since the disease may not be differentiated simply from physiologic hypogammaglobulinemia of infancy, on the one hand or from acquired agammaglobulinemia on the other. Nevertheless it is apparent that the congenital disease shows an overwhelming preponderance in the male sex. The few cases reported in female infants may be early examples of acquired agammaglobulinemia. Gitlin, Janeway, Apt, and Craig [63] have diagrammed three kinships in which are found five proved and four presumed cases of agammaglobulinemia. These genealogies are reproduced in Fig 45-3. In all instances the relationship between affected individuals is that of brothers or nephew and maternal uncle. Occurrence of cases in brothers is noted by Good and Zak [57] and in cousins by Porter [64]. The observations give strong support to the belief that congenital agammaglobulinemia is inherited as a sex linked recessive characteristic.

### OTHER INHERITED VARIATIONS IN PLASMA PROTEIN PATTERNS

Recent investigations utilizing the starch gel electrophoresis procedure described by Smithies [65] have brought to light several other variations in plasma protein patterns which appear to be inherited characteristics. None of these anomalies appears to be associated with any disease. Smithies and Walker [66] showed that normal human serums could be divided into three types on the basis of differences in the patterns obtained by their method of analysis. It soon became clear that the protein fractions on which this differentiation was made were the previously described haptoglobins, normal constituents of the serum which have the peculiar property of binding hemoglobin. These haptoglobin types have proved to be hereditary characteristics but the precise genetic mechanism of their transmission is not clear. An interesting hypothesis that might explain the findings is offered by Allison [67]. Individuals whose serum contains no haptoglobin have also been encountered [68] but it has not yet been shown that the defect has a genetic basis.

Several recent reports describe the findings of familial variants in the  $\beta$  globulin components revealed by starch gel electrophoresis. Smithies [69] found evidence for the occurrence of three types of  $\beta$  globulin and a recent communication by Harris, Robson, and Smiraglio [70] increases the number to five. All subjects so far reported have in their serum the  $\beta$  globulin designated C and in most individuals this protein predominates. In a number of Negroes and Australian aborigines however a slower moving protein designated D by Smithies [69] comprises about half the  $\beta$  globulin. In a few Caucasians a roughly equal amount of a faster moving component called B has been encountered. That these

variants are hereditary is shown in genealogies given by Smithies [69] and by Harris et al [70]

Fraser Harris and Robson [71] have reported the presence in one family of a plasma protein not usually seen in human plasma. The nature and significance of the component have not been elucidated but it appears not to have any detrimental effect on the members of the family who have it.

Finally, mention should be made of the occurrence in one small family group of an abnormally great thyroxine binding capacity of the serum  $\alpha$  globulin. This anomaly recently reported by Bierswales and Robbins [72] seems to be of clinical significance only because it results in an unusually elevated protein bound iodine value in euthyroid subjects. In one individual discovered by Tanaka and Starr [73] an unusually low protein bound iodine level seems to be related to the absence of thyroxine binding protein. There is as yet no evidence for a familial tendency or genetic basis for this defect.

### OTHER HYPOPROTEINEMIAS

Familial defects in plasma protein constituents are either responsible for or closely associated with several diseases discussed in other chapters of this book (Chaps 25, 30, and 44). In addition there is the hitherto poorly defined entity of idiopathic hypoproteinemia. Many such cases have been shown to have a defect allowing loss of macromolecules from the plasma into the gastrointestinal tract. This defect can be conveniently demonstrated with  $I^{131}$  labeled polyvinylpyrrolidone [74]. Actual loss of protein into the lumen of the stomach has been well demonstrated in one case studied by Citron, Sterling and Halsted [75]. The hypoproteinemia resulting from this protein losing gastroenteropathy should not at present be considered a biochemical lesion and no hereditary trend has yet been demonstrated.

An unusual family several members of which had abnormal serum protein patterns by electrophoresis was described by Homburger and Petermann [76]. It seems unlikely that the situation described is actually a hereditary biochemical anomaly since the manifestations were so varied and since many of the cases had protein concentrations which differed only slightly from the normal. The more severely affected individuals may actually have had protein losing gastroenteropathy if so they will comprise the first family group known to be so affected.

### SUMMARY

1. A number of variations in plasma protein patterns are known to be inherited characteristics. Some involving the absence of a protein are

associated with disease. Other conditions involving only a minor change in the chemistry of the protein while demonstrable by examination of the serum, do not produce any deleterious effects. The important hereditary protein anomalies are as follows:

2. Analbuminemia is an extremely rare condition characterized by failure of albumin synthesis. The affected subjects have mild edema but are otherwise well. There is virtually no albumin in the serum, and laboratory tests that are affected by serum protein concentrations are abnormal. Albumin replacement therapy is satisfactory and probably beneficial. The mode of inheritance has not been established, but the condition is probably transmitted by a recessive gene.

3. Agammaglobulinemia is characterized by a marked reduction but usually not total absence of  $\gamma$  globulin. Since the subjects are unable to form antibodies, they are unusually susceptible to bacterial infection, the consequences of which dominate the clinical picture. Antibiotic and  $\gamma$  globulin replacement therapy are helpful. Agammaglobulinemic patients lack plasma cells, the normal source of antibodies. The clinical disease may be acquired or congenital. The congenital form appears to be transmitted as a sex-linked recessive characteristic.

4. There are several conditions characterized by minor alterations in the chemistry of one or another plasma protein. These variants are detected by electrophoresis on paper or starch gel. None is associated with illness. This category includes double albumin anomaly and the genetically controlled variants in  $\beta$  globulins and haptoglobins.

## Chapter 46

### Acatlasia\*

---

James B. Wyngaarden and R. Rodney Howell

Acatlasia is a rare hereditary condition presently recognized in man only among the Japanese [1-5] though also known to occur in certain breeds of dogs [6] and guinea pigs [7]. The disorder was first described in 1949 by Takahara and Miyamoto. Three years earlier Takahara, a Japanese otorhinolaryngologist, noted that the operative field in a maxillary sinus from which he was removing a putrid tumor turned brown black upon the addition of hydrogen peroxide and did not foam. He also noted that blood from this patient turned dark brown on contact with peroxide. Investigation revealed that her blood lacked catalase and that several of her family members had the same defect.

The disorder was initially designated *acatalasemia* but since it is now known that catalase is absent from liver, muscle, and bone marrow as well as from the blood, the designation *acatalasia* [8] is preferred and will be used in this chapter to specify the entity. The term *acatalasemia* will be employed descriptively only.

### CLINICAL SYNDROME

Thirty-eight cases of acatalasia have been recognized in 17 Japanese families [4, 5]. About one-half have exhibited a peculiar and characteristic oral gangrene. In these patients gum and mouth infections occurred usually before age 10, and small ulcerations of the gums were observed as early as the second or third year of life. In some patients these ulcerations receded but were followed by new lesions which encroached upon the dental alveoli, thereby loosening the teeth. After the teeth fell out or were extracted, healing frequently occurred but in some instances gangrene with sequestration ensued. Extensive erosions into the maxillary

\* This work was supported in part by grant CY-4142 from the Public Health Service.

sinus or the mandible sometimes led to development of putrid granulating tumors. Surgical intervention and bone grafting were then required. All degrees of ulceration occurred from minor erosions which healed readily to extensive oral gangrene. At times ulceration and necrosis involved the tonsil or the tongue. Recurrent episodes of gangrene at various sites in the alveoli with intermittent healing have continued for as long as 10 years [3]. Except for the oral lesions and fever in the presence of infection physical examinations were negative. Leukocytosis was not reported although mild anemia was observed. The absence of severe anemia indicates that the synthetic defect is not primarily one of heme elaboration. Treatment was directed toward excision of the gangrenous tissue and eradication of oral infection. After all teeth were removed and lesions had healed many patients were permanently free of symptoms.

*Illustrative Case (from Takahara [1])*

An 11 year-old girl presented with pain in her mouth. Three years earlier small ulcers had begun to appear on her gums. Some healed spontaneously but they were soon succeeded by others which spread to involve the dental alveoli thus loosening the teeth. When the teeth fell out or were removed healing occurred. After extraction of a tooth some weeks prior to her admission a sequestrum developed at the site of the tooth. Gangrene followed and progressed despite medical treatment. The right cheek swelled causing severe pain and a fever of 101 F developed.

The patient was a pale girl with greatly swollen and slightly reddened cheeks. The gums about her remaining teeth were gangrenous. Erosion of the right maxilla extended into the maxillary sinus and nasal cavity and produced a foul odor. Aside from a slight fever the physical examination was negative. Hemoglobin was 65 per cent of normal, red blood count 3,450,000 per cu mm. Erythrocyte sedimentation rate was 35 mm per hr. Bleeding and clotting times were normal and serologic examination was negative.

The right nasal cavity contained a foul friable granulating tumor. A biopsy specimen showed only chronic inflammation. Following radical removal of the tumor and curettage hydrogen peroxide was applied to the operative site whereupon the cavity in the maxilla and the surface blood immediately turned brownish black. Irofs or Takahara supposed silver nitrate had been applied by mistake promptly washed the wound with saline solution and applied hydrogen peroxide from a new bottle only to observe a repetition of the color change. He then noted that the black color was caused by blood oozing from the wound and that very few bubbles had formed.

The postoperative course was complicated by three recurrences of sequestrum formation necessitating curettage but the lesions healed completely in 2 months. One year later ulceration recurred at the site of the extracted teeth and despite treatment again progressed to development of gangrene.

After a month of therapy which included surgical drainage the disease was checked. Nine months later another recurrence with sequestration was successfully treated with penicillin. Subsequently the patient's remaining teeth were pulled whenever ulcers appeared in her gums. At the age of

15 she was edentulous but fully developed and apparently well. Investigations revealed absence of catalase in her erythrocytes and oral mucosa.

Further investigations revealed that three of five siblings of the patient also lacked catalase in their blood. Two of them had the same oral disease as the patient. A further disclosure was that the parents were second cousins.

### CATALASE STUDIES

When hydrogen peroxide solution is dropped into normal blood, gas is evolved and the color does not change. When hydrogen peroxide was dropped into the blood of the patient described above it blackened immediately and gas did not appear [1]. Blood from three of five siblings gave an identical response. These observations suggested to Takahara that blood catalase was deficient. Using Warburg's manometric method [9, 10], he established that catalase activity was indeed grossly deficient in blood and also in oral tissue obtained from these patients. The results of his initial studies on five patients are shown in Table 46-1, they indicate a virtual absence of catalase activity in both types of tissue in these subjects. Subsequently, confirmatory results were obtained in studies of blood of additional patients by a permanganate titration method [11, 12]. The values in all patients suspected of lacking catalase by the qualitative test approached zero when analyzed by quantitative methods. Blood peroxidase levels were normal in all patients [1].

When a small quantity of  $H_2O_2$  was added to acatalasemic blood in a

test tube the blood remained black for a long time. If an excess of peroxide was added the blood began to lose its dark color in 20 to 30 min and became light reddish brown then lemon yellow and finally colorless. This solution was shown to contain propentdyopent = colorless decomposition product of hemoglobin. When this solution was made alkaline with potassium hydroxide heated and reduced with sodium dithionite ( $\text{Na}_2\text{S}_2\text{O}_4$ ) = beautiful rose color developed [1]. This rose colored compound previously named *pentdyopent* by Bingold [13-14] because of its absorption maximum at  $525 \text{ m}\mu$  is now known to be = dipyrrole [15]. The colorless precursor named *propentdyopent* by Fischer and von Döbeneck [16] is a closely related substance. The probable structures of these compounds [17] and their relationship to hemoglobin are shown.

Takahara next ingeniously correlated the pentdyopent reaction observed in the test tube with biologic events involving bacteria isolated from the oral cavities of affected patients [1]. He prepared blood agar plates with normal and acatalasemic blood and planted hemolytic streptococci or pneumococci type I obtained from an acatalasemic subject on these plates. These two organisms were the predominating organisms in the mouth lesions of most of the subjects with acatalasia. The colonies grew equally well on both types of agar but on the acatalasemic blood agar wide transparent rings appeared around the colony instead of hemolytic rings growing larger with time. These colorless zones showed a positive pentdyopent reaction! This study showed that peroxide was produced by the = organisms in quantities sufficient to destroy hemoglobin in the blood agar lacking catalase.

Kaziro and associates [8] analyzed selected tissues from an asymptomatic adult patient with healed oral lesions and known acatalasemia. They found no catalase activity in biopsy specimens of liver, muscle and bone marrow although catalase activity was demonstrated in these tissues from = control subject. Although this does not constitute exhaustive proof that all viscera are devoid of catalase in patients with acatalasemia these results and those of Takahara showing absence of catalase in oral mucous membranes of such patients provide strong evidence for this likelihood. Kaziro et al interpreted their data as evidence for a

"constitutional acatalasia" and proposed the term *anerymia catalasica* for this genetic anomaly. The simpler term *acatalasia* is here proposed as nomenclologically preferable to *acatalascemia* and as an etymologically acceptable designation for this genetic anomaly.

## CATALASE

Thénard [18] noted in 1818 that both plant and animal tissues degrade hydrogen peroxide, a substance he himself had discovered some years earlier. Loew [20] in 1901 gave the name 'catalase' to the substance responsible for this degradation. In 1923 Warburg [2] suggested that catalase is an iron-containing enzyme because it is inhibited by cyanide. Evidence that its prosthetic group is hematin was offered in 1930 by Zeile and Hellstrom [21]. Catalase was crystallized from beef liver in 1937 by Sumner and Dounce [22] who reported an iron content of about 0.1 per cent and emphasized that the prosthetic group is heme or a closely related substance.

### The Prosthetic Group

Catalase activity is widely distributed in mammalian tissue but is most abundant in liver, kidney, and erythrocytes [23-24]. Catalase has been crystallized from these three tissues of a number of species [24-26], including man [26-28], as well as from bacteria [29]. Animal catalase is an iron porphyrin protein with a molecular weight of 220,000 to 250,000 containing four porphyrin nuclei and four atoms of iron per molecule (0.09 per cent) [30-31]. Several authors [32-33] believe that different catalases exist containing 4, 3, 2, 1, and 0 hematin groups and 0, 1, 2, 3, and 4 verdohematin groups. However, Bonnichsen has suggested that the oxidized porphyrin groups are post mortem artifacts or changes occurring during isolation and has reported that human liver [26-27] and erythrocyte [34] catalases have no verdohematin groups. In human catalase as in beef liver catalase the porphyrin nucleus is the ferric complex of protoporphyrin IX (corresponding to etioporphyrin isomer type III) (protohematin) [35]; it is identical with that found in horse radish peroxidase, methemoglobin, and metmyoglobin and is similar to that of ferri cytochrome C. The differences in chemical nature and physiologic role of these iron porphyrin proteins are attributed to differences in the protein moieties and in the character of linkages between protein and prosthetic group. The structure and biosynthesis of protoporphyrin IX are discussed in Chap. 30.

The catabolism of the heme of catalase is apparently identical with that of hemoglobin and ultimately yields bilirubin [36]. The ferriprotoporphyrin of catalase is easily removed from the apoenzyme by acid acetone recombination has not yet been achieved [37]. The enzyme gives

pectroscopically characteristic derivatives with cyanide fluoride azide and other anions and with its substrate hydrogen peroxide

### *The Apoenzyme*

Theorell and Åkesson [38] determined the nitrogen distribution and basic amino acids of horse liver catalase Bonnichsen [34] compared horse liver and blood catalases and found them to contain identical quantities of histidine arginine lysine glutamic and aspartic acids and amide nitrogen Immunologically there was no difference between them and

TABLE 46- AMINO ACID COMPOSITION OF BOVINE LIVER CATALASE

| Total         |                   | 1,748                  |

SOURCE: From G. Schnuchel [39].

in the ultraviolet their absorption coefficients were the same. Horse blood catalase differed from human blood catalase immunologically.

Recently Schnuchel [39] published a complete amino acid analysis of crystalline bovine liver catalase (Table 46-2). It contains 18 amino acids and 1,748 amino acid residues and more histidine and lysine than were reported for horse liver catalase [34, 38]. Thus regardless of the interpretation of differences in the porphyrin prosthetic groups it is clear that catalases of different species vary in the composition of the apoenzyme.

### *Tissue Catalases*

Theorell and associates [40] investigated the origin of liver and blood catalase in guinea pigs using  $Fe^{55}$  and  $Fe^{59}$ . Activity in liver ferritin

initially exceeded that in liver catalase but approached equal labeling at about 10 days and thereafter declined in parallel. Blood catalase in contrast showed a slower increase that ran parallel to the hemoglobin iron activity. They concluded that identical enzymes were being formed in different organs. The short life cycle of liver catalase suggested to Theorell [19] that the verdohematin prosthetic groups previously found in liver catalase [32, 33] may be normal intermediates in the destruction of catalase.

Additional evidence for independent origins of heme of liver and erythrocyte catalases is provided by studies of Schmid, Ligen, and Schwartz [41]. The administration of allylisopropylacetyl carbamide (Sedormid) to rabbits and rats causes simultaneously a marked and rapid fall in liver catalase activity, a great increase in liver porphyrin concentration and porphyrinuria. No significant change occurs in erythrocyte catalase activity, in hemoglobin concentration or in activity of liver cytochrome oxidase and succinic dehydrogenase. Studies with glycine-2- $C^{14}$  suggested that Sedormid blocks formation of catalase in liver; the porphyrin accumulations in liver and urine were viewed as possible consequences of this block. The observation that daily excretion of porphyrins and their pyrrole precursors exceeded the amounts of catalase heme normally found in liver may be a reflection of the extremely rapid turnover of liver catalase. It also suggests that catalase or a product of it may normally exert a feed back regulatory effect upon hepatic porphyrin synthesis.

Finally, levels of catalase activity of liver can be varied experimentally but those of erythrocytes remain constant under a variety of circumstances. Among the factors which selectively reduce catalase activity of liver or other viscera are starvation [42], iron deficiency [43], copper deficiency [43], castration (in male rats only) [44], adrenalectomy (in rats of both sexes enhanced by prior castration in the male) [44], endogenous [45] or transplanted [46] tumors, nitrogen mustard, carcinogens or hepatotoxins [47]. Elevations of liver catalase activity are produced in adrenalectomized rats by cortisone and in castrated male rats by testosterone. Both hormones are required for complete restoration of normal activity in castrate adrenalectomized male rats. Testosterone increased kidney and liver but not blood catalase activity in normal female mice [44].

In severe human iron-deficiency anemia there is no change in catalase activity per milliliter of erythrocytes although there is a slight decrease per million red cells [48]. If it is assumed that catalase and hemoglobin derive heme from a common source [40] these results indicate that catalase synthesizing mechanisms compete successfully for a limited amount of heme under conditions of iron deficiency. In iron deficiency in animals catalase activity of heart remains normal despite a decline in activity in other viscera [43].

Only one abnormal value of blood catalase activity was noted in 152 patients with a variety of disorders. Similar analyses in diseased animals gave only normal results [49]. Blood catalase is said to be elevated in acute malaria and normal in the chronic phase [50].

### CATALASE FUNCTION

#### *Decomposition of $H_2O_2$*

It was originally thought that catalase served as a physiologic safeguard to decompose  $H_2O_2$  which might otherwise accumulate within the cell. Bingold [51] suggested in 1933 that the role of erythrocyte catalase was to protect hemoglobin from oxidation by  $H_2O_2$ . It was shown that inhibition of catalase by hydroxylamine permitted rapid oxidation of hemoglobin to methemoglobin when peroxide was added. Keilen and Hartree [52] reasoned that the violent decomposition of  $H_2O_2$  in Bingold's experiments generated much  $O_2$  and maintained hemoglobin as oxyhemoglobin in which form its iron is resistant to oxidation. They demonstrated formation of methemoglobin despite the presence of abundant catalase activity when  $H_2O_2$  was generated slowly by a glucose oxidase system. Since this experiment simulated conditions *in vivo* they concluded that catalase does not function to protect hemoglobin.

#### *Peroxidatic Activity*

In 1936 Keilen and Hartree [53] demonstrated coupled oxidation of ethanol in the presence of a peroxide generating system (xanthine oxidase and hypoxanthine) and catalase. It is now well established that with high substrate concentrations of low molecular weight alcohols, formaldehyde or formic acid, and low concentrations of peroxide, catalase exhibits peroxidatic activity.

Chance [54, 55] has studied the mechanisms of the actions of catalase. The initial reaction involves formation of a complex between catalase and  $H_2O_2$  in which peroxide is bound to the ferric iron of heme.

The enzyme substrate complex can then react with a hydrogen donor—a peroxidatic reaction:

Or it can react with a second molecule of  $H_2O_2$ —a catalatic reaction:

The catalase-hydrogen peroxide complex has been identified spectrophotometrically in aerobically respiring cells of *Micrococcus lysodeikticus*. The steady state intracellular hydrogen peroxide concentration in these organisms was calculated to be  $10^{-8} M$  [57, 58].

### Physiologic Roles

Chance believes that catalase acts both catalatically and peroxidatically *in vivo* [56] and has pointed out [57] that the partition between catalatic and peroxidatic utilization of hydrogen peroxide will depend mainly upon the steady state peroxide concentration. The velocity of the catalatic reaction increases linearly with the peroxide concentration; the peroxidatic reaction is essentially independent of peroxide concentration. Catalase may thus act as a regulator of hydrogen peroxide concentration; small amounts of peroxide will saturate the peroxidatic function, larger amounts are decomposed in the catalatic reaction. The peroxidatic action of catalase requires only very low concentrations of peroxide, about  $10^{-6}$  M. Thus at a steady state concentration of  $10^{-8}$  M, as in *M. lyso deikticus* [55, 56], catalase is probably acting by a combination of the catalatic and peroxidatic pathways.

Since physiologically there may exist high concentrations of other acceptors and low concentrations of peroxide, it is conceivable that catalase serves primarily as a peroxidase in animal tissues and only secondarily as a defense against accumulation of peroxide. Indeed the catalatic reaction  $2\text{H}_2\text{O}_2 \rightarrow 2\text{H}_2\text{O} + \text{O}_2$  may be viewed as merely a special case of a peroxidatic reaction where hydrogen peroxide serves both as substrate and as acceptor. Theorell [19] has proposed that both catalatic and peroxidatic enzymes be called *hydroperoxidases*, to emphasize that they have a common substrate  $\text{H}_2\text{O}_2$ .

Catalase is not absolutely specific and will act upon organic peroxides such as ethyl hydrogen peroxide under certain circumstances [58, 59]. Its rate of decomposition of hydrogen peroxide is the highest of any enzymatic rate studied to date. One molecule of catalase is capable of splitting 42,000 molecules of  $\text{H}_2\text{O}_2$  per second at  $0^\circ\text{C}$ .

Catalase is inactivated in 10 min at  $60^\circ\text{C}$  but is stable at  $4^\circ$ . It is inhibited by a large number of compounds, some of which do not affect other heme protein enzymes. In hemolyzates of normal blood, inclusion of 2,4-dichlorophenol to inhibit catalase permits demonstration of the peroxidatic action of methemoglobin [60] which will then result in rapid oxidation of uric acid (or other suitable acceptor) in the presence of peroxide. Hematin split from catalase by acid acetone will function peroxidatically but not catalatically in this system, demonstrating the essential contribution of the catalase protein to its catalatic activity [61].

### HYDROGEN PEROXIDE

The sources of hydrogen peroxide become important in consideration of the pathogenesis of the oral lesions of subjects with acatalasia.  $\text{H}_2\text{O}_2$  is produced by aerobic dehydrogenases—enzymes which transfer hydrogen

directly to molecular oxygen of which several are found in mammalian tissue. All the enzymes of this series employ flavin adenine dinucleotide (FAD) as coenzyme, and occur as cytoplasmic constituents. A number have also been identified in the insoluble particles of liver presumably the mitochondria. Peroxide formation then must be a normal occurrence in mammalian cells.

The important aerobic dehydrogenases of mammalian tissue are monamine oxidase, diamine oxidase,  $\beta$ -amino acid oxidase, L-amino acid oxidase, glycine oxidase, glycolic oxidase, xanthine oxidase, and uricase, although the last enzyme does not occur in human tissue.

That coupled peroxidatic reactions of the types discovered by Thurlow [62] and by Keilen and Hartree [59] may be of physiologic significance was shown by Heppel and Porterfield [63] who found sufficient hydrogen peroxide produced in rat liver homogenates to promote a readily measurable oxidation of nitrite to nitrate by catalase.

Aerobic dehydrogenases occur in bacteria also, and production of  $H_2O_2$  has been detected in several aerobic organisms which contain no catalase, such as pneumococci, *Bacillus acidophilus*, and certain streptococci [51].  $H_2O_2$  is presumed to occur in other aerobic or facultative anaerobic organisms also, but to escape accumulation because of the presence of catalase, which is known to exist in *Escherichia coli*, *Bacillus subtilis*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and others [51].

## PATHOGENESIS OF LESIONS OF ACATALASIA

Individuals with acatalasia show no signs of ill health other than mouth lesions. When all teeth are lost or removed, and the lesions treated, healing occurs and the individuals remain well thereafter. Some subjects with acatalasia are asymptomatic throughout their lives. These observations strongly imply that oral sepsis initiates the ulcerative, gangrenous process, and that individuals with acatalasia are vulnerable to attack by ordinarily innocuous bacteria of normal oral flora.

### Local Lesions

Takahara [1] reasoned that gums are apt to be injured during mastication, and that wounds in gums are suitable media for bacteria. The most commonly cultured organisms, hemolytic streptococci and pneumococci type I, are producers of hydrogen peroxide and lack catalase. In persons who lack catalase in blood and oral tissue, serious effects result, because hydrogen peroxide oxidizes blood reaching the lesion, thus depriving the infected area of oxygen and causing necrosis. This would favor multiplication of bacteria, increased production of peroxide, and oxidation of hemoglobin.

Additional factors may be involved [8]. Several other potential effects

of peroxide on tissue should be considered, such as possible actions upon sensitive heme proteins. Activity of catalase has been observed to decline in high concentrations of peroxide in the presence of a reducing substance, probably because of autocatalysis of oxidation of the protohematin groups to bile pigment hematin groups [33]. In the absence of catalase similar changes might well involve tissue peroxidases, cytochromes, and myoglobin. Production of metmyoglobin would render it incapable of binding  $O_2$  in muscle. Recently, even higher valence states of iron (ferryl myoglobin) [64], or production of free radicals of myoglobin through loss of hydrogen from the conjugated ring system of the porphyrin moiety [65] have been attributed to hydrogen peroxide.

Dixon [66] showed that catalase protects xanthine oxidase from destruction by the hydrogen peroxide which it forms. This may be an example of the well known susceptibility of flavin prosthetic groups to destruction by peroxide or it may illustrate a general effect of peroxide on proteins. Peroxide will oxidize sulfhydryl groups potentially all the way to sulfonic acid residues, and a large percentage of enzymes depend upon sulfhydryl groups for functional activity.

Peroxide is hemolytic [67]. It is also known to oxidize directly a number of compounds found in cells, e.g.,  $\alpha$  keto acids. Thus a large number of effects in addition to destruction of hemoglobin may be anticipated if tissue lacking catalase is exposed to hydrogen peroxide.

### *Systemic Effects*

About one half of the subjects with acatalasia are asymptomatic, and many of the others remain entirely well when mouth lesions have healed. Initially it was not known that tissue catalase was also absent and it remained possible that subjects with acatalasemia lacked catalase only in blood and in injured oral mucous membranes. Had this been so, these subjects would have had a catalase distribution like that of the duck, in which blood lacks catalase but other tissues have abundant activity of this enzyme [8]. With the demonstration of absence of measurable catalase activity of other tissues in an asymptomatic subject with acatalasemia it became clear that catalase was not an indispensable enzyme and that in its absence toxic levels of  $H_2O_2$  did not accumulate. Thus an experiment of nature has answered one important question and it is now clear that catalase does not serve as an essential physiologic safeguard. One might wonder whether subjects with acatalasia would show increased levels of methemoglobin in circulating erythrocytes but in one analysis such an increase was thought questionable [8].

Recently it has been shown that peroxidases are widely distributed in mammalian tissue [68] and presumably these enzymes utilize such peroxide as is produced as substrate for their oxidative functions. It will be recalled that peroxidase was normal in acatalasemic blood pre-

sumably representing peroxidatic activity of leukocytes [69-70]. Consumption of peroxide in such reactions apparently is quantitatively sufficient to prevent peroxide toxicity even in the absence of catalase unless infection with catalase free organisms supervenes.

## TREATMENT

Treatment of oral lesions has been highly successful in preserving life and in eventually controlling the progression of the necrotic changes. Surgical excision of granulating tumors, curettage, drainage and irrigation of septic areas, extraction of teeth and antibiotic therapy have been employed. Reconstructive surgery and bone grafts have been required. The direct application of crystalline catalase suspensions for control of acute lesions has been suggested [71]. The effects of transfusions of normal whole blood containing catalase would also seem worthy of evaluation.

## GENETICS

The 38 known cases of acatalasia occurred in 17 families living in various parts of Japan. In all but 3 families 2 or more siblings were affected. In 2 families as many as 4 siblings were affected. A history of consanguineous marriage was obtained from 16 families. Of the 38 cases 19 occurred in males and 19 in females. The first pedigree discovered containing 13 cases of acatalasia have been reported in detail [1, 2]. In each one (or more) consanguineous marriage was found a total of 9 in all. In 3 families both parents and children with acatalasia were living and were studied. Not a single parent had acatalasemia. Also in 1 family 12 of 15 children of 3 acatalasemic members were tested and none had acatalasemia. These findings virtually exclude dominant inheritance.

The findings of consanguinity, involvement of families at one sibling level only and equal sex distribution are suggestive of non sex limited recessive inheritance. In a study of 27 of 31 members of 5 sibships including known acatalasia subjects 13 acatalasemic and 14 normal members were found [1, 2]. If one excludes from analysis the 5 probands the finding of 8 acatalasemic subjects among 22 siblings is in satisfactory agreement with an anticipated incidence of 25 per cent homozygous abnormal in individuals from a nonlimited recessive inheritance.

Catalase assays have been done on the blood of 66 members of 5 families [72] by a modification of the method of von Euler and Josephson [73-74]. The distribution of values of activity units was clearly trimodal (Fig 46-1). In 10 subjects values were zero; in 30 they ranged from 1.48 to 2.89; in the remainder they were comparable to values in 206 control subjects which ranged from 3.91 to 7.10. Thus subjects exist in these

families who show intermediate values of catalase activity which do not overlap with values for the controls. Presumably these are 'carriers' heterozygous for the acatalasia trait. This investigation showed that (1) the parents of acatalasemic subjects are hypocatalasemic, (2) the

Fig 40-1 Distribution of catalase values for members of five acatalasia families and comparison with a percentage distribution curve of values from a normal control group (By permission of E. T. Vishimura et al and Science [2])

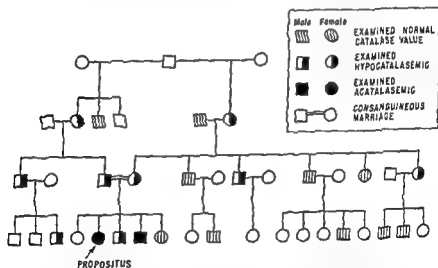

Fig 40-2 Genealogic relationships in an acatalasia family (Redrawn from E. T. Vishimura et al [2] Reproduced with permission of authors and publisher)

siblings of acatalasemic individuals may be acatalasemic, hypocatalasemic, or normal. (3) an acatalasemic parent has hypocatalasemic children when mated to a normal person. These findings and those of an expanded study recently published [7a] appear to document fully the earlier conclusions of Takahara and coworkers [2, 3] that acatalasia is transmitted by incompletely recessive monogenic inheritance. A typical genealogic diagram appears in Fig 40-2.

Allison Rees and Burn [6] noted variations in blood catalase activity in a large group of dogs of various breeds. In some dogs activity values were quite low and blood darkened on the addition of  $H_2O_2$ . Controlled breeding of these animals disclosed a simple mode of recessive inheritance for which a single pair of alleles was proposed. Heterozygous dogs showed values of blood catalase intermediate between those of homozygous animals and those of normal dogs. Tissue catalase values were not reported.

Radev [7] obtained similar genetic results in a study of guinea pigs with normal and low blood catalase activity values. Animals with low blood values were also found to have low catalase activity values in their livers. No signs of ill health were noted in either guinea pigs or dogs with low catalase activities.

## SUMMARY

1 Acatalsia is a rare hereditary disorder presently recognized only among the Japanese in which ulcerating gangrenous lesions of the oral cavity may be observed. The oral mucous membranes, erythrocytes, liver, muscle and bone marrow of affected individuals lack catalase activity.

2 The lesions appear to be caused by the destructive effects of hydrogen peroxide generated by catalase free bacteria growing within the mouth. In subjects with acatalasia hydrogen peroxide injures oral tissue possibly by destruction of structural and enzymatic proteins through oxidation of their sulfhydryl groups, by oxidation of heme proteins such as hemoglobin, myoglobin, peroxidases and the cytochromes and by oxidation of flavoproteins.

3 Acatalsia may be entirely asymptomatic and affected persons whose teeth are removed and whose lesions have healed may thereafter be entirely well. Catalase appears to be a nonessential enzyme except for the protection it affords against  $H_2O_2$  generated by bacteria.

4 Acatalsia is transmitted as an autosomal recessive Mendelian characteristic. Consanguinity has been found in most pedigrees of acatalasia. The distribution of blood catalase activity values in 66 members of 5 families was clearly trimodal and no overlap was observed. The intermediary values presumably defined individuals who were heterozygous for the acatalasia trait. Both parents, some siblings and all children of acatalasemic subjects were heterozygous by this criterion.

5 An apparently analogous disorder of catalase synthesis with similar genetic characteristics has been described in certain breeds of dogs and guinea pigs. Heterozygous dogs show blood catalase activity values intermediate between those of normal and homozygous animals. Guinea pigs with low blood catalase activity values also show low activity in liver

## Appendix

### Methods of Coding and Filing Family Records

---

Grace J. Yesley

The student of human genetics who is confronted for the first time with an extended pedigree or a collection of moderate sized pedigrees rapidly acquires a healthy respect for the problems inherent in ordering such data. Over a period of 15 years the Department of Human Genetics of the University of Michigan has developed a system of recording and coding pedigree data that has proved of convenience in the study of hereditary disease. This appendix constitutes the first description of that system. The system is composed of three principal sections (1) a numerically arranged *Kindred Folder File* (2) a *Surname Card File* and (3) a *Diagnosis Catalogue*.

#### KINDRED FOLDER FILE

By placing all information on a kindred (pedigree results of any examinations performed etc.) in a folder each kindred record may be easily separated from the records of other kindreds. As the number of kindreds on file accumulates it becomes advantageous to develop an efficient filing system so that (1) records of all kindreds which have a person or persons involved with some particular disease may be quickly taken from the files for examination and study and (2) it may be rapidly ascertained if a person or his family has already been seen at the Clinic.

By assigning a kindred number to each kindred the records may be filed numerically. Advantages of this system over an alphabetic system of filing are apparent to anyone who has worked with an alphabetic system and been faced with the problem of frequently having to shift almost all the records to make room for those new records which are continually being placed within the system.

*Pedigree*

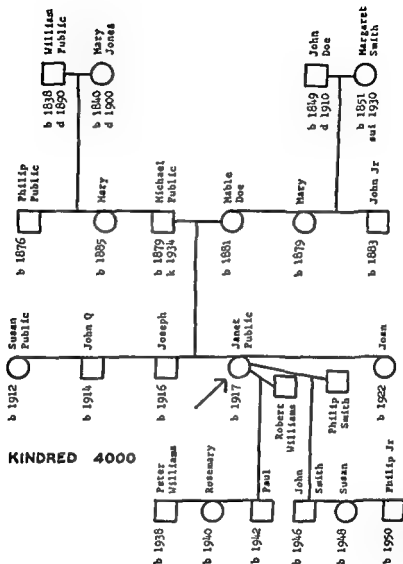

A pedigree is the backbone of any study of hereditary disease. It may be presented in a number of acceptable forms. The conventions employed at the Department of Human Genetics, University of Michigan Medical School, have proved to be useful and informative, and are accordingly described here. The members of each sibship are recorded in the order of their birth, with the eldest on the left and the youngest on the right, with a few exceptions which will be discussed later. Every pedigree has as a focal point (indicated by an arrow) the *propositus*, the person who initially brought the kindred to the attention of the physician or geneticist. The pedigree then is built around this *propositus*.

The male ancestors of the *propositus* and his relatives are drawn on the left and the female ancestors and her relatives on the right (Fig. 1). To facilitate the drawing and eventual reading of the pedigree, an exception is made to the general rule of arranging members of a sibship in their birth order with respect to the parents of the *propositus*: the male parent is drawn at the end of his sibship and the female parent at the beginning of her sibship, irrespective of birth order (Fig. 1). Each ancestral sibship is also drawn in this manner, with the male ancestors at the end of their sibships and the female ancestors at the beginning of their sibships. Sibship lettering starts with the sibship of the *propositus* (Sibship A) and ascends from left to right from that sibship through the sibships of the grandparents. Sibship letters A through G then have definite meaning, with Sibship B always referring to the father's sibship, D to the paternal grandfather's sibship, etc. (1). The letter H is always reserved for the sibship containing the offspring of the *propositus*. I, J, K, . . . W may be used for any ancestral lines beyond the grandparents which are of special interest.

At this stage, all sibships descending from the siblings of the ancestors and the siblings of the *propositus* are identified by the sibship lettering of their parents (the parents biologically related to the *propositus*) with one letter added. That is to say, sibships which are first-generation descendants of Sibship B would be labeled BA, BB, BC, etc., with Sibship BA being the offspring of the eldest member of Sibship B, BB the offspring of the second eldest, etc. By strict adherence to this coding system in all records, one may at a glance determine the exact genetic distance from the *propositus* of any relative whose sibship lettering starts with a letter from A to H [i.e., BA, BB, BC, etc. = paternal first cousins; CA, CB, CC, etc. = maternal first cousins; BAA, BAB, BBA, etc. = paternal first cousins once removed (offspring of paternal first cousins); DAD, DBA, DBB, etc. = paternal second cousins, etc.].

Other occasionally needed and therefore standardized codings are as follows:

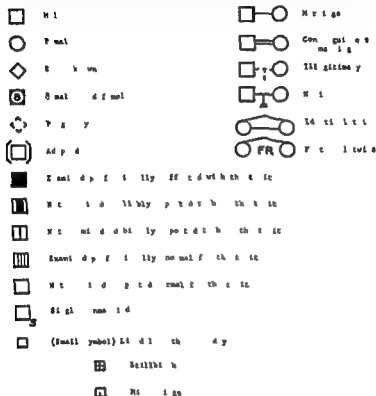

# KINDRED 4000

APPENDIX FIG 1 Hypothetic pedigree illustrating the method used for including names of biologic relatives and spouses birth and death dates

The names of all biologic relatives of the propositus are customarily written above the sibship line and the names of unrelated persons (spouses of relatives) are written below the sibship line. Birth and death dates are written below the symbol of each person.

Although every individual develops his own method of taking notes during interviews, there are in general two approaches to this problem.

APPENDIX FIG. 3. Symbols frequently used in drawing pedigrees.

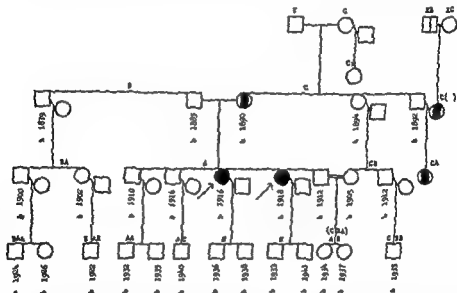

The family history may be taken in pedigree form, all the pertinent information being given on the pedigree, or in outline form, the data being jotted down by sibship in the sequence in which the pedigree is assembled. Figure 3 illustrates the standard shorthand symbols used in drawing pedigrees.<sup>1</sup>

The above steps provide the basic structure of the pedigree coding system with methods for handling the common problems. From this point on, the problems become more or less specific to the clinic physician or geneticist using the system, modifications of or additions to the

1 2 (subscripts) = half siblings ( $H_1$  = half siblings of  $H$ ,  $H_2$  = half-siblings of  $H$  and  $H_1$ , i.e., children of a third marriage by the parent in common to  $H$  and  $H_1$ .)

Y, Z = off-spring of per on adopted into the family (persons of little or no genetic interest in the study of that particular family but often valuable as informants)

At times one encounters a family in which consanguineous or affinous (relationship between persons through another marriage but not through

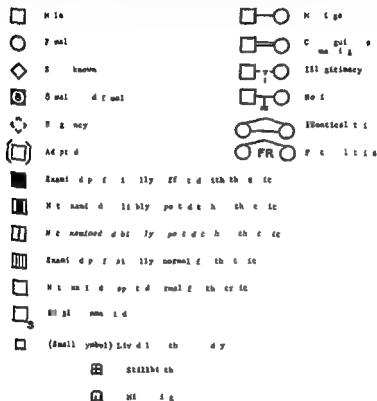

Appendix Fig 2 Hypothetic pedigree illustrating sibship lettering system

a blood line ) marriage has occurred. Often these relationships may be more readily illustrated if the siblings are drawn out of strict birth order. Consanguineous marriages are by convention indicated by a double marriage line. Figure 2 illustrates a consanguineous marriage between a man in Sibship 1 and a woman in Sibship CB. Here then is another valid exception to following the eldest to youngest rule established earlier. In the case of consanguineous marriages occurring in a kindred one often has a choice of two possible sibship lettering codes for the offspring. Thus offspring from the union referred to above could be designated with either a sibship code of 1B (derived from the father's sibship code) or CBA (derived from the mother's sibship code). The code derived from the parent who is more closely related to the propositus is the one used. In Fig. 2 the father in the consanguineous union is a sib of the propositus; the mother is a first cousin--thus in this case, the sibship code is derived from the male parent and is therefore 1B.

The names of all biologic relatives of the probandus are customarily written above the sibship line and the names of unrelated persons (spouses of relatives) are written below the sibship line. Birth and death dates are written below the symbol of each person.

Although every individual develops his own method of taking notes during interviews, there are in general two approaches to this problem:

APPENDIX FIG 3 Symbols frequently used in drawing pedigrees

The family history may be taken in pedigree form, all the pertinent information being given on the pedigree, or in outline form, the data being jotted down by sibship in the sequence in which the pedigree is assembled. Figure 1 illustrates the standard shorthand symbols used in drawing pedigrees.<sup>1</sup>

The above steps provide the basic structure of the pedigree coding system with methods for handling the common problems. From this point on, the problems become more or less specific to the clinic physician or geneticist using the system, modifications of or additions to the

<sup>1</sup> Dice Lee R. Symbols for human pedigree charts. *J Heredity* 37:11, 1946.

system may prove of benefit to meet these specific needs. It is convenient to file at least four special forms with the pedigree as follows:

1 *Case Record Sheet* The Case Record Sheet is the front piece of each kindred folder. This sheet contains the following information: genetic problem, name of *propositus*, kindred number, origin (how the kindred came to the attention of the Department), date of ascertainment, additional ascertainments and their dates, name of person who conducted the interview, and addresses of members in the kindred.

2 and 3 *Comment Sheet* and *General Information Sheets* respectively. If there is very little family history, all the information may be recorded on the Comment Sheet and the General Information Sheets may be omitted. If there is a more extensive family history, family history is recorded by sibship on the General Information Sheets and the Comment Sheet is used by the interviewer to express his opinion concerning the reliability of the information obtained from the informant and the advisability of doing further work with the family.

4 *Office Operations Sheet* The Office Operations Sheet is a progress check sheet. It contains a list of all the procedures to be carried out before the kindred folder is ready to be filed.

## SURNAME CARDS

Identification of individuals within kindreds has always presented a complexity of problems. Numerous types of name-card files have been set up with varying degrees of success. The system developed by the Department of Human Genetics, University of Michigan Medical School, has proved almost 100 per cent effective. The file is a 'surname file' in which all members of one kindred with the same surname are recorded by sibship on the same 3- by 5-in. card *Surname Cards* for the hypothetical kindred shown in Fig. 1 would appear as reproduced in Fig. 4. The surname is placed in the upper left hand corner and the kindred number in the upper right hand corner. By examining the *Public* card and comparing it with the pedigree in Fig. 1, it can be seen that each person who uses or has ever used the name 'Public' is recorded on the card (in birth order when more than one individual in a sibship is listed). Within the body of the card, the name 'Public' is abbreviated to 'P' in the cases of married females and is omitted but understood to be at the end of the names of all males and all single females. Since the *propositus* is the focal point of the kindred, her name is underlined for emphasis. If a given name or a surname is unknown, a dash may be used in its place. Thus — Wright Phillips would be the name of a woman whose given name is unknown, whose maiden name is Wright and married name is Phillips. Other examples are Mary — Phillips (maiden name unknown) and Mary Wright — (married name unknown).

APPENDIX FIG 4 Surname Cards obtained from pedigree in Fig 1

If a woman bears a child out of wedlock and the father is known this may also be indicated on the Surname Cards. For example if an unmarried woman named Mary Jones bears a child (Tom Jones) whose father is Frank Smith Mary's name would be recorded

Mary Jones (Smith) ( Mrs Frank Smith)

and Tom's name would be recorded

Tom (Smith) Jones

Thus a surname in parentheses is one which was never used by the individual but which at the same time has a certain amount of biologic importance, if the unused surname is unknown it may be recorded (—) with the parentheses indicating unused and the dashes indicating unknown. Quotation marks around a surname indicates that the surname is or has been in use by that individual. It may be an assumed name, a name acquired when the person was adopted, or a maternal surname the use of which is contrary to the custom in this country. Legally Tom's surname is Jones but the use of the mother's surname is a break from the

tradition of our society, in which the child has the same surname as the father, and is therefore enclosed in quotation marks

Surname Cards are filed in a phonetic alphabetic system combining the surnames which are either the same or almost the same phonetically. Thus as an example, cards for the surnames of Allman Ahlman, Ahlman Allmond, Alma, Almond, Ammon, Lmen Ullman and Ammons or of Baers, Baer, Baher, Bahers, Bahr, Bahrs, Bair, Bairs Bear, Bears Beer Beers, Bearss, and Behr would be filed as a unit, alphabetically under the most common surname in the group

As soon as one starts filing Surname Cards in a phonetic manner within an essentially alphabetic system, he must devise a system to keep those

APPENDIX FIG 5 A Guide card which precedes phonetically filed surname Cards—located in file in the alphabetic location of Ulrich B Guide card which follows phonetically filed Surname Cards C Index card which is filed alphabetically in place of Surname Cards with the surname of Audtrich Audtrich surname Cards have been filed alphabetically under Aldrich

phonetically filed cards together as a unit and at the same time make it very apparent that the cards are out of alphabetic order so they will not be used as guides for filing subsequent cards. One half-cut separator guide cards are used to separate that group from the cards filed alphabetically before and after the group. The key name (ideally the most common name in the group) determines where the group is to be filed. It is typed in upper case letters on a card with a second place cut and all other surnames to be filed within this group are typed in lower case on the same card (Fig 5A). A blank first place cut index card is then placed at the end of the group to separate it from the other cards in the file (Fig 5B).

For the names filed out of alphabetic order by being placed in one of these groups 3 by 5 in cards of a color different from the regular Surname Cards are filed in the system where those names would appear if they had been filed in alphabetic order. On these cards is typed information which will direct one to the proper place in the file (Fig 5C).

With this system in use the name of every individual in every kindred

appears in the name file with a minimum use of space. By having all relatives with the same surname on one card one can more readily determine whether a newly ascertained person is already on file. This is a very important tool in the case of more common surnames. Many Mary Smiths may be on file but the number of Mary Smiths with a brother John is much more limited.

The diagram shows five overlapping cards, each representing a different first name within the Smith family. The cards are arranged in a descending staircase pattern, showing how they would be filed together. Each card contains a header with the surname and a list of individuals with their identifiers and names.

APPENDIX FIG. 6 Typical First name Cards

In the files of the Department of Human Genetics, University of Michigan Medical School, approximately 1 out of every 20 kindreds has at least one person who has or has had the surname of Smith. It is apparent that as the files increase in size a further refinement of the system is advantageous in dealing with some of the more common surnames. First name Cards are typed for the surnames that are common to at least 20 kindreds. Thus all Mary Smiths on record are entered on a Mary Smith card, all John Smiths on a John Smith card, etc. Figure 6 illustrates typical First name Cards. These cards are filed alphabetically by given name immediately after the Smith Surname Cards and are separated from the rest of the file by one-fifth cut guide cards of a different color.

tradition of our society, in which the child has the same surname as the father, and is therefore enclosed in quotation marks

Surname Cards are filed in a phonetic alphabetic system combining the surnames which are either the same or almost the same phonetically. Thus as an example, cards for the surnames of Allman, Ahlman, Alhman, Allmond, Alma, Umond, Aramon, Limen Ullman and Ammons or of Baers, Baer, Baher Bahers, Bahr, Bahrs, Bair, Bairs, Bear, Bears Beer Beers, Bearss, and Behr would be filed as a unit, alphabetically under the most common surname in the group

As soon as one starts filing Surname Cards in a phonetic manner within an essentially alphabetic system he must devise a system to keep the

APPENDIX FIG. 5. I Guide card which precedes phonetically filed Surname Cards—located in file in the alphabetic location of Aldrich II Guide card which follows phonetically filed Surname Cards C Index card which is filed alphabetically in place of Surname Cards with the surname of Audtrich Audtrich Surname Cards have been filed alphabetically under Aldrich

phonetically filed cards together as a unit and at the same time make it very apparent that the cards are out of alphabetic order so they will not be used as guides for filing subsequent cards. One half cut separator guide cards are used to separate that group from the cards filed alphabetically before and after the group. The *key name* (ideally the most common name in the group) determines where the group is to be filed, it is typed in upper case letters on a card with a second place cut and all other surnames to be filed within this group are typed in lower case on the same card (Fig. 5A). A blank first place cut index card is then placed at the end of the group to separate it from the other cards in the file (Fig. 5B).

For the names filed out of alphabetic order by being placed in one of these groups 3 by 5 in. cards of a color different from the regular Surname Cards are filed in the system where those names would appear if they had been filed in alphabetic order. On these cards is typed information which will direct one to the proper place in the file (Fig. 5C).

With this system in use the name of *every* individual in *every* kindred

Suppose at some future date a young man named Mark Smith should present himself for examination. In an interview with him it is learned that he has siblings named John, Philip and Susan Smith. Smith First name Cards for these four names (Mark, John, Philip and Susan) are pulled from the files and compared to see if any of the people listed have any common kindred number and sibship coding. On the John, Philip and Susan cards it is noted that each card lists an individual belonging to kindred 4 000 who is in Sibship H<sub>1</sub> (Fig. 6) but there is no Mark Smith listed in kindred 4 000 H<sub>1</sub>. However with this amount of positive correlation, the information obtained from Mark and that contained in kindred 4 000 should be compared—birth dates, other names and addresses are all of help in determining whether or not the kindreds are one and the same. In this example there were three positive correlations. However, in attempting to trace relationships it is sometimes helpful to compare records with as few as two positive correlations. If Mark had supplied no information about siblings but did state that his mother's name was Janet Public Smith, a card in the file with Janet — Smith (woman with given name of Janet, maiden name unknown, married name of Smith) would supply one positive correlation. A card in the file with the name "— Public Smith" (a woman whose given name is unknown, maiden name is Public and married name is Smith) would also supply one positive correlation. Thus the location of the name Janet Public Smith in the file (Fig. 6) would supply the two positive correlations required for further checking.

## DIAGNOSIS CATALOGUE

With the increase in number of records on file a Diagnosis Catalogue becomes a helpful tool for locating all kindred records relating to a particular disease. This catalogue could be of loose leaf notebook or card type depending on how much information is to be recorded about each kindred. Each disease is recorded on a separate sheet or card; these are kept in alphabetic order. Since many clinical entities may be referred to by more than one name (imperforate anus vs. atresia ani) or may be alphabetized under more than one word (Patellar nail or Nail patellar syndrome) a list of the synonyms of diseases already on file should be kept so that any disease apparently not yet in the catalogue may be checked against this list. It has proved helpful to have the following information on each diagnosis sheet: trait kindred number, kindred name (surname of the propositus or in the case of a married female, maiden surname plus married surname), year of examination, type of inheritance, number examined and affected with the disease, origin and remarks.

Wassermann 86

formation of 63

in urine 76

Urea and ribonucleoside 718

Urea and ribonucleoside deficiency 718

synthesis of 719

Urea and blood phosphorus 63

absorption by intestine 734 736

Urea and 705

Urea and 1074 776 1407

normal detection limit 681

Urea lyase 724

by biotin 76

nitrogen 724

rate of 724

urea 713 724

urea 724

Urea and diphosphoglycerate (UDPG)

Urea and nucleotide biosynthesis 615

Urea and triphosphoglycerate (UTP) glycerate 4

pathway 94

Urea and 784

nitrogen 16

Urea and nucleotide biosynthesis 77

Urea and 397

in tissue 1276

osmolarity of 1275 183

normal blood level 184

analysis of 18

production of 118

Urea and 971

defect in protein synthesis 971

analysis of 43

in myoglobin 946

in hemoglobin 1016

in hemoglobin 945

Urea and 939

Urea and 395

Urea and 184 184 468

primary hypoglycemia 40

Uroporphyrin 939 95

in blood and urine 96

in blood and urine 943

in blood and urine 943

in blood and urine 943

in blood and urine 961

in blood and urine 941

in blood and urine 93

Uroporphyrinogen decarboxylase 951

in blood and urine 93

in blood and urine 93

in blood and urine 953

in blood and urine 953

in blood and urine 953

in blood and urine 93

in blood and urine 93

in blood and urine 93
